The chapters on potential field and electrical methods are rather less satisfactory, giving undue emphasis to instruments, interpretation methods and units now best consigned to the museum: for example, several obsolete methods for the interpretation of resistivity soundings could well have been given as references only, saving space for the 'resistivity transform' approach to this problem. These chapters also assume some knowledge of vector calculus, but the rest of the book should present no mathematical difficulties even to readers trained primarily as geologists.

It is still true that no single textbook is sufficient for the education of a graduate geophysicist, but this one is certainly necessary for reading and reference. At little more than a penny a page in paperback, it has the advantage of being within his means.

Martian geology

The Geology of Mars. By T. A. Mutch, R. E. Arvidson, J. W. Head, K. L. Jones and R. S. Saunders. Pp. ix+400. (Princeton University: Princeton, New Jersey, 1977.) £28.40; \$35.

WRITING a book about our planetary companions in the Solar System is, and has been for over ten years, a hazardous business. The rate of exploration has been such that inevitably parts of such a book are out-of-date even before it arrives on the bookstands; this is because new, important and often revolutionary information is returned from another exciting space mission. Despite this, and despite the fact that we are in the middle of the highly successful Viking mission to Mars, Thomas Mutch and his colleagues have produced an extremely timely book on the geology of Mars. Essentially, it summarises our knowledge of this planet up to the time of Viking, although it does include pictures and information from the early part of the Viking mission slipped into the book at the last moment. The book is a valuable contribution to planetary studies because it provides (as did Glasstone's *The Book of Mars* before Mariners 6, 7 and 9) an up-to-date summary of our knowledge of this fascinating planet up to the time of Viking—a useful time to stop and take stock of the situation.

The book opens with two chapters describing early telescopic observations and the history of spacecraft exploration of Mars. This is followed in the third chapter by a summary of the major physiographical provinces of Mars and a discussion of how each of the landforms characteristic of different parts of Mars may have been formed. The main bulk of the book consists of individual chapters on surface processes including impact cratering, volcanism and the action of wind and water, all of which have played a part in producing the martian surface as we see it today. There are also discussions of geophysics, structure and geological history of Mars.

Geologists not involved in planetary studies have often been disappointed with new discoveries from both the Moon and Mercury because so much of the geology of these planets is dominated by impact cratering, a geological process of interest to only a few specialists. This is not true of Mars as, although the ancient southern hemisphere of Mars is dominated by impact cratering, the northern hemisphere and poles show abundant

evidence of other processes more familiar to the terrestrial geologist. Large areas have been modified by wind erosion and deposition, and the desert geomorphologist cannot fail to be impressed by the extensive dune fields exposed on the martian surface. Winding channels are indicative of water erosion and the areas around the polar caps show thick sequences of layered rocks. Although volcanism probably played an important part in the evolution of all terrestrial planets, it is only on Mars and Earth that we have seen such a variety of large constructs of high topographical relief. Extensive patterns of rifts and faults show that the tectonic history of Mars has been quite unlike that of the Earth and an understanding of this is essential to developing a general theory for planetary tectonics.

Molecular potential energy surfaces

Symmetry Rules for Chemical Reactions: Orbital Topology and Elementary Processes. By R. G. Pearson. Pp. ix+548. (Wiley-Interscience, New York and London, 1976.) \$31; £17.50.

THE title of this work is not altogether successful in describing the contents. I do not venture to suggest a better one; but Professor Pearson's concern is with the nature of molecular potential energy surfaces generally, and with their influence on the shapes of molecules as well as on the courses of reactions. His thesis rests on two main principles. The first, due principally to Bader, although certainly used earlier, is that a distortion of a particular symmetry is favoured by the presence of a low-lying electronically excited state of a related symmetry. (Perhaps this should be called the 'Bader effect' since the usual 'second-order Jahn-Teller effect' is a clumsy and inaccurate term.) The distortion may lead a molecule from one postulated structure to another, in which case one obtains an understanding of the shapes of molecules. Walsh's rules are usefully approached in this way. Alternatively, the distortion may initiate a reaction, in which case one obtains an understanding of the relative ease of alternative reaction paths.

The second principle is that of "orbital correlation" or "conservation of orbital symmetry": the symmetry species of the molecular orbitals in reactants and products must match. If they do not, then at least one bonding orbital in the reactants correlates with an anti-bonding orbital in the products,

The authors of this book do an excellent job of summarising and discussing critically our knowledge of all these subjects. They also briefly compare Mars with the other planets, including Earth, showing how all the solid planets in the Solar System are important field areas for Earth-bound geologists.

This book will not only be a useful reference book for planetary geologists but provides an easily readable and well illustrated review for the non-specialist. For a student it is an important text, although sadly the price is high (especially the sterling equivalent); and students may have to rely on library copies. **J. E. Guest**

J. E. Guest is Lecturer in the Department of Physics and Astronomy at University College, London, UK.

which in turn implies a high activation energy. In the application of these principles, a third is used: the predicted behaviour depends on the "orbital topology"—the nodal structure of the molecular orbitals—which is not significantly modified even if the symmetry is broken by irrelevant changes to the molecule. Consequently symmetry-based methods may often be used where no formal symmetry is present.

Professor Pearson expounds these principles with admirable clarity and numerous examples. The Jahn-Teller selection rule is incorrectly stated (the correct version is subsequently used, but with no explanation of the notation for the symmetrised square) and the account of the first-order Jahn-Teller effect contains some very dubious remarks. Fortunately, the first-order Jahn-Teller effect is of only peripheral importance in the later development. A more general criticism is that the magnitudes of the effects cited are not always shown to be sufficient to account quantitatively for the observations. For example, the dissociation energy of ozone is 1 eV, whereas that of sulphur dioxide is 5.5 eV; this is explained by the fact that the relevant excited state in ozone is at 4.7 eV, whereas the corresponding state in sulphur dioxide is at 5.3 eV. The difference is in the right direction but the numerical values are unconvincing.

For the most part, however, Professor Pearson approaches his subject carefully, critically and thoroughly. This is a stimulating and valuable book, and an important contribution to a rapidly developing field of research.

Risk adviser: mission impossible?

AN idea that has received wide publicity in the past week or two has been the concept of an independent community risk advisory service. Professor Gordon Atherley, of the University of Aston in Birmingham, presented the idea to the Council for Science and Society's meeting on acceptable risk and proposed that the council should take some initiatives itself to establish such a service. For its part, the council, in its forthcoming report on the acceptability of risks, commends the idea—'only in such a way can there develop an involvement of people experiencing risks, which is so necessary for fair decisions and effective control'.

There are many attractions to the idea. Professor Atherley envisages the scheme being staffed by a small band of volunteers with a scientific training who would agree to attend 'clinics' regularly in local communities to listen to and advise on problems connected with risk. The council suggests a full-time paid adviser, using part-time help. The concept would certainly be moving with the social tide, which is undoubtedly flowing away from monolithic centralised organisations towards local, more informal bodies. And analogies can be found, for instance in community law centres set up to help those who might be overawed by the legal establishment or its fees. The intention is that in the main the adviser would act as a source of information, maybe doing a little monitoring or research himself or herself. The proposal is clearly thoroughly worthy, in keeping with the council's previous institutional suggestions. But the question is, is it workable?

It is certainly going to tread on a few toes. The relationship of 'risk' to pollution, infectious diseases, safety at work, hygiene, public order, nuclear safety, fire and explosive hazards and road and rail safety is going to be hard to define. In all of these there are already deeply entrenched interests working at local or national level; it is certainly not clear that such interests, many of which have an excellent if unpublicised track record, will take at all kindly to a new figure in the community. This need be no bad thing if the community risk adviser were able to pursue an independent course of research, but this is most unlikely—in many matters the adviser will have to depend on these very organisations for data and even interpretation. Can this be done without the generation of ill-will or corruption? Of course a risk adviser would

ideally be on the lookout for new risks for which no control mechanism yet existed and might, for instance, have some success in the field of noise; but in most other fields he or she might need almost extra-sensory perception to foresee the extraordinary ways in which risk appear.

However attractive the idea of spreading information about risks around the community in the same way that a legal service answers questions about the law and a consumer bureau provides ratings of relative value for money, there is a danger that the function of a specifically risk-oriented agency would be misunderstood as a place where answers would be given. And then, of course, the community would quickly turn on an adviser whose subjunctive-ridden replies had been misunderstood as authoritative pronouncements and proved wrong by later events. Would this make for a fulfilling job for a community risk adviser? It is perhaps in questions about the calibre of a person who would do such a job that we have the most serious reservations. Unpaid volunteers, says Professor Atherley; £3,500 per year, says the council—it is difficult to be serious about a scheme relying so much on voluntary involvement or modest salaries. The community risk adviser would have to be such a paragon of virtue, so widely knowledgeable, so unswayed by pressure groups, so diplomatic in dealing with toe-trodden agencies, so tough in living with decisions, that it is doubtful that many likely candidates exist.

That a community risk adviser may not be the way to go does not, however, close the issue. The social tide is still flowing and the public is bound to want to know more and not less about hazards and nuisances. An immense amount of expertise already exists in the existing agencies and it seems desirable that before we set up yet another we should look very carefully at how well the present agencies present themselves to the public. It is as yet by no means clear whom one should write to, phone or go and see when worried about potential or actual hazards. More informative telephone directories, advertising on television and in newspapers would all help to encourage the public to take a less Kafkaesque view of governmental agencies. If in a few years there was no growing sense of public participation in coming to terms with risks, then it might be time to try and set up a risk advisory service. But let the present agencies show their paces first. □

International science (1): NATO

Plain-clothes science

Chris Sherwell, recently at NATO,
looks at the alliance's science programme

WHAT is NATO? To most people it is simply the western alliance, the collection of fifteen nations formed after the Second World War for the purposes of mutual defence. Others see it as much more. For instance, when Jimmy Carter delivered his keynote address at the recent NATO summit in London, he saw the alliance as political and economic as well as military—which of course it is.

Indeed, NATO has always been these things and more. So broad is it that, to the amazement of many western scientists, it stretches as far as a civilian science programme. In the vast concrete labyrinth of buildings and corridors that are NATO's European headquarters in Brussels, there is a handful of offices occupied by a friendly group of what in other continental circles are usually called 'committed Europeans' because of their internationalism. There are just over half a dozen of them, and they discharge responsibilities created almost a decade after the North Atlantic Treaty was signed in 1949.

That treaty, which is most explicit about the threat of war and the resolution of disputes, contains in Article 2 vaguely worded sentiments about a better understanding of the principles upon which free institutions are founded. At the end of 1956 a committee of three foreign ministers—Lester Pearson (Canada), Gaetano Martino (Italy) and Halvard Lange (Norway)—produced a report on non-military cooperation. Like the devil and sin, they were for it; in particular they argued that science and technology was "one area of special importance to the Atlantic community".

From this and further suggestions by these so-called 'Three Wise Men' for recruiting and fostering contact between scientists, was born a Task Force on Scientific and Technical Cooperation. That was in July 1957. Then, fortuitously, came the single most important event to ensure the future of a NATO involvement in civilian science: the launching of the first Soviet Sputnik in October 1957. Two months later the Task Force reported its findings to the heads of government. Its recommendations were predictable.

The future of the West, the Task Force proclaimed, was dependent to an ever-increasing degree on the rate at which science and technology advanced. It was therefore in NATO's

interest to do all it could "to bring about the general conditions which will accelerate the pace of scientific progress"; deficiencies in science and technology should not be allowed to hamper the effort to strengthen NATO members' economies and defences.

Committee plus adviser

That was the reasoning, and it was accepted. Institutionally it produced NATO's Science Committee and a Science Adviser to the NATO Secretary General who was soon called Assistant Secretary General for Scientific Affairs. He is now Professor M. Nimet Özdas from Turkey, a mechanical engineer by training; he has occupied the position since 1973 and is the eighth holder of the post. Among other things, he chairs the Science Committee, on which sits one representative for each country (the SRC head, Sir Sam Edwards, represents Britain, for example); it met for the first time in March 1958 and, unsurprisingly, there are plans afoot for a Commemoration Conference next spring to mark NATO's 20 years in the business. What form that will take remains unclear as yet. What business NATO has been in is available for anyone to see.

One business it is not in with its science programme is defence-related research, save in a most indirect and thus unimportant sense. That activity falls under a separate division of NATO altogether. Because of his position Özdas is aware of work being done, but it has little to do with the nuts and bolts of his science programme. Özdas does say the security of the alliance is important as a purpose behind NATO's science programme, but then he could hardly be expected to say otherwise. The programme's direct impact is confined largely to the scientific community it seeks to help. Indeed, a cursory examination of the work supported and the cushioned impact it has outside scientific circles suggests that NATO's involvement in science is as benign as that of practically any other funding agency.

If there is any keynote, it is collaboration. Next to publication, collaboration is seen as the essential ingredient for the progress in modern research that is NATO's expressed concern. But NATO is anxious that it should do things which aren't already done and that this should happen

without at the same time adulterating in any way the established standards that ensure quality work.

It is admitted that the latter has not always been achieved—that in earlier days mistakes were made and NATO could have acquired a reputation for being a 'soft touch'. But its peer review system has been tightened up in recent years. If charmed circles of researchers who know the system extract money more easily than others, it isn't easy to prove. The system is open to anyone, and the criteria are clear. Where there is abuse, the only sanction at NATO's disposal is to refuse money the next time round.

Altogether, six fragments make up NATO's efforts to stimulate scientific cooperation. A Science Fellowships Programme, coordinated by Bulent Bayraktar, who is from Turkey, consumes the bulk of the Science Committee budget of some \$9 million. In this field Özdas believes that NATO is unique. No other organisation, international or otherwise, is funding the international exchange and foreign training of young postgraduate and postdoctoral students on such a scale (500–600 fellowships a year).

The focus of the second biggest consumer of funds, the Advanced Study Institutes (ASI) Programme, is higher up the academic ladder. Again emphasising international aspects and seeking to do something unique, the programme aims to provide high-level tutorials and seminars on selected topics, usually of an inter-disciplinary character, on the basis that such matters might not otherwise be covered and the people involved in them might not otherwise come together.

NATO funds some 50–60 applicants a year who are themselves responsible for organising the ASI. Each ASI usually lasts up to a couple of weeks and can involve as many as 30 lecturers and 100 participants. The coordinator of the programme from Brussels, Tilo Kester, a German, receives applications each year running into hundreds which must be refereed after initial screening. The \$30,000 or so that each ASI costs goes entirely on travel and living expenses; the direct benefit gained by the organiser is chiefly in the form of a publication.

International collaboration between scientists is further encouraged by the Research Grants Programme. International collaboration, in fact, is the *sine qua non* for participation in the programme, which offers financial aid to joint projects that involve laboratories and institutes in different countries. What NATO tries to do is fill the gaps left in respect of travel by national grants.

Some 75% of the money disbursed goes on living and travel expenses, and

the awards, which are also determined through peer review, are now of the order of \$4,000 where they were once up in the \$30,000 bracket. Demand has increased in recent years, and the programme's coordinator, Mario di Lullo from Italy, insists that the prospect of publishing either one or several papers is not a passport to a successful application, even though publications are expected to have a NATO credit.

Two relatively minor activities funded out of the Science Committee budget are the Senior Scientists Programme, which awards a small number of senior fellowships and visiting professorships each year, and the Science Committee Conference Programme, which, unlike other programmes, is organised directly from Brussels. Less than a dozen of these special conferences on particular topics have been held.

The sixth fragment of NATO's science activity is intentionally the least general but it is no less complex to administer. It breaks down into six parts. Known collectively as Special Science Programmes, they complement the other programmes and are designed to ensure coverage of specific topics. These include marine science, eco-science, air-sea interaction (a meteorology programme ended in 1972), materials science, systems science and behavioural science.

Seventh fragment

Özdas has another important position. This stems from a decision taken at NATO's twentieth anniversary meeting of heads of government in 1969 to create the Committee on the Challenges of Modern Society (CCMS). Özdas chairs this committee, which operates in an interesting way to avoid expensive, secret and centralised direction.

The CCMS has no budget. If any study is to be conducted, there has to be a pilot country or countries to shoulder the responsibility, probably with other countries as 'co-pilots'. They provide the funding, and they do the study. It is carried out on the basis of information readily available, with a short time horizon in mind. And for the most part it is conducted in an open fashion with participation not just by interested organisations within the alliance countries but also by countries outside the alliance—including the USSR and East Europe.

The CCMS proposes, the NATO Council approves. Eight studies have been completed and another eleven are under way. Topics include pollution, disaster assistance, health care, energy and so on.

Özdas is assisted in the discharge of his duties by Dr Philip Hemily, an American. A man sincerely concerned to know current trends in thinking

about contemporary problems, he is realistic enough to know the limits of NATO's capacity to help solve them. Of both the virtues and pitfalls of NATO's involvement in science he and his colleagues are only too aware. But they remain committed to the ideals which inspire scientific research, and see a role for NATO.

Thus, asked the obvious question, "Why NATO?", their immediate response is equally obvious: "Why not?" Pressed further, they steer clear of

arguments about common defence and security, preferring to fall back on another point: that there are no apparent alternatives available. No other international body is apparently working to oil the wheels of scientific research by providing finance to encourage international collaboration. That becomes their most positive argument: in the jargon of the men at NATO, they are 'action oriented'. And there is no doubt in their minds that the action is needed. □

International science (2): OAS

Science for progress

Mahindra Naraine traces the history of the OAS's involvement in science in Latin America

THE Organisation of American States (OAS) is probably the least well known of the major international organisations. United States hegemony over the nations in the western hemisphere has resulted in scant attention being paid by 'outsiders' to the OAS and its operations. Yet it is interesting that the OAS is the oldest international organisation of its kind in the world. Not only that; for the past ten years it has also had a Scientific and Technological Programme. With a budget in 1976 of about \$10 million (about 20% of the OAS budget), this programme supports such work as the development of solar refrigeration in Mexico, the study of fur seals in Uruguay, computer technology in Brazil and deforestation studies in Haiti. In comparison with this the science and technology efforts of some other organisations seem puny.

Although the OAS has been in existence for some time its main pre-occupation has been the idea of hemispheric peace, naturally under the guiding hand of the United States. The Cuban revolution and the Kennedy Administration together helped to speed up efforts aimed at the economic sector. The much-acclaimed Alliance for Progress, set in motion in August 1961 at Punta del Este (Uruguay), had the intention of eradicating economic under-development in Latin America. By the late 1960s corruption and maladministration minimised the potential benefits of the influx of some \$1,000 million into the region. The programme did not work well, and by 1967 it was obvious that a political boost to the OAS was necessary.

The American Chiefs of State met that year and in the 'Declaration of Punta del Este' stated that their aim was the creation of a Latin American Common Market. This was to begin in 1970 and to be in operation no later than 1985; it was to be a convergence of the then existing Latin American Free Trade Association and of the Central American Common Market system. The declaration also expressed the intention of harnessing science and technology for the service of the Latin American peoples. To effect this it was decided to establish a Regional Scientific and Technological Programme (PRDYCT). It was also stated that because of the magnitude of the

investments required for science and technology, it was necessary to have inter-American cooperation.

In compliance with the Punta del Este Declaration, the Inter-American Cultural Council formally established PRDCYT in February 1968. In this Resolution of Maracay it was stated that PRDCYT

... shall be oriented towards the adoption of measures to promote scientific and technological research, teaching and information, basic and advance training of scientific and technical personnel, and exchange of information. It shall intensively promote the transfer to and adaptation by the Latin American countries of knowledge and technology originating in other parts of the world.

PRDCYT was not the first programme of a technical nature to exist in the OAS. As far back as 1950 a programme of Technical Cooperation was created to deal with requests for technical assistance. With the advent of the Alliance for Progress there was a rapid expansion of technical assistance projects. The OAS then established a special training programme in which, for the first time in OAS history, countries outside the hemisphere could participate. Several European countries participated, but the most significant contribution in this category has come from Israel. In 1975, for instance, Israel provided 70% of the experts for technical co-operation from non-member countries. Mechanisms for the operation of

PRDCYT were somewhat predetermined by the imperatives of integration and infrastructure. PRDCYT set out to create centres of excellence for the training of personnel from all the member countries. Three mechanisms were involved: multinational projects, supporting actions and basic studies.

Multinational projects are activities that are carried out in one or more centres in the region with the cooperation of several or all member states. Activities could be of a regional, sub-regional or national character. Regional activities are carried out in selected centres and in general consist of special courses, seminars and other types of technical meetings. Activities within the national sphere are meant for institutional development and to improve research and education. The OAS identified two kinds of centres: a responsible centre operated as headquarters for regional activities and provided assistance at a national level to less well endowed centres; centres that received these benefits were called participating centres.

For the less well endowed centres 'supporting actions' were expected to strengthen the scientific and technological infrastructure by building up equipment and other resources. The third mechanism, basic studies, was meant to obtain information on the region's scientific and technological capability and development.

Main emphasis

In the early years of PRDCYT the main emphasis was on multinational projects. These were allocated about 60% of the budget, in keeping with the big push for Latin American integration. There were multinational projects on mathematics, physics,

A union of American Republics has existed since 1890 but it was only in 1948 that a Charter was drawn up and the Organisation of American States created. The OAS consists of 25 member countries spread over two continents and six islands in the Caribbean. Cuba still remains a member but in 1962 was excluded from participation in OAS affairs.

Early attempts were made by Simon Bolivar to develop the ideal of regional solidarity, but these failed. It was not until the Monroe Doctrine and the idea of the Western Hemisphere as the region of United States influence that hemispheric unity, even if somewhat unbalanced, was feasible. The OAS has therefore suffered the criticism that most of its actions have been for the benefit of the dominant partner—the US.

OAS headquarters are in Washington; 18 of the member countries are Spanish-speaking. Other related OAS organisations include:

The Pan American Health Organisation (PAHO). Based in Washington, this was founded in 1902 and promotes and co-

ordinates hemispheric efforts to combat disease, lengthen life and promote health in general. PAHO also serves as a regional agency of WHO and maintains close relations with the national health services in member countries. In 1974–75 its budget was \$34 million.

The Inter-American Institute of Agricultural Sciences (IICA). Founded in 1942 with headquarters in Costa Rica, it is the specialised unit of the OAS for agriculture and does teaching, research, technical assistance and conservation. Its activities are spread over the four geographic zones of the region. IICA manages the Simon Bolivar fund set up for rural development.

The Inter-American Nuclear Energy Commission (IANEC). This is a technical commission set up in 1959 to serve as a centre of information and consultation for the member states and to offer them the necessary cooperation and assistance for the peaceful uses of nuclear energy. The commission is financed mainly by funds from the regular budget of the OAS.

Mahindra Naraine is a Nature Travelling Scholarship holder.

chemistry, genetics, biochemistry and so on. Not all the countries benefited equally from the project, however. The more developed countries had had a greater exposure to science and made more use of the new opportunities.

The main criticism, however, came from Latin American academics, mainly social scientists. Continued pressure resulted in the OAS sponsored 'Conference on the Application of Science and Technology to Latin American Development' (CACTAL). This conference was held in 1972 in Brazilia and its recommendations, called the Consensus of Brazilia, had a major impact.

Essentially CACTAL posited that development of a scientific and technological infrastructure that was not very closely linked to the productive sector was fruitless. What was important was that national science policies be closely coordinated with economic and social policies. There must be removal of technological dependence on the developed nations, indigenous technologies had to be developed, teaching and research should be geared to the labour market and the productive sector, scientific and technological development should give preference to the rural and urban marginal sectors and national science policies should look at such matters as patents, trademark legislation and technology transfer agreements.

The OAS noted the resolutions and attempted to modify its programme. The OAS 'Mar del Plata Resolution' acknowledged that the structure of PRDCYT was too rigid to meet the demands of the member states in a timely manner. It recommended that more attention be paid to economic and social development; for this there would be a revision of the fields of action and types of activities. It was agreed that there was an urgent need for scientific and technological development in the developing countries; for this a special Mar del Plata fund was created giving preference to them.

Funding

The nature of the funding of OAS activities is somewhat complex. There is an OAS general fund to which all members contribute according to quotas established by the OAS secretariat. The total budget for 1961 was \$8.3 million. In 1968 it was \$17.2 million and in 1975 \$56.5 million.

PRDCYT is administered by the Permanent Executive Committee of the Inter-American Council for Education, Science and Culture (CEPCIECC). CEPCIECC works out a budget for its fiscal period in line with previous years and proposed projects. Members are then asked to

pledge amounts to this CEPCIECC fund in a similar ratio to the OAS general fund. Contributions are voluntary. Typical ratios are 0.19% for the poorest countries, 7.4% for countries like Brazil and Argentina, and 66% for the United States.

The CEPCIECC budget is for science, education and culture. Until 1974 PRDCYT was allocated 60% of the budget but this figure has since been reduced to 50%. It has been said that the change is a consequence of most of the representatives on CEPCIECC being Ministers of Education. In its first year of operation PRDCYT was allocated \$2.4 million excluding administration costs. In the first three years the programme disbursed some \$18 million. For the next five years over \$50 million was spent.

The funding has been further complicated by the creation of the Mar del Plata fund in 1974. Under this each country has a multiplier factor; the poorer the country, the higher the multiplier. Countries whose quota to the general OAS fund is less than 0.75% have a multiplier of about 7; for a country like Mexico it is 1.9. A country then allocates money to this special fund providing it does not exceed the sum it contributes to the regular fund. This contribution is then increased by the multiplier factor; the matching funds are made up mainly by the United States. For the 1974-76 period the Mar del Plata account had some \$5.8 million.

At the present time PRDCYT acts in areas of basic and applied sciences (supporting the funding of research projects and training of personnel), technological research and the transfer of technology. It is also involved in scientific and technological policy and planning—helping in the formulation of national science policies.

Applications for support are sent through the national science agencies to the OAS. The OAS has a panel of experts which provides technical guidance on the application. Projects can request training of personnel, recruitment of visiting professors, equipment, books and so on, but do not cover administration expenses or other requirements. In compliance with political attempts at integration, however, preference is given to projects that are multinational, so that proposals always include provision for contact or assistance with other regional institutions or personnel.

Main problem

Ironically, PRDCYT's main problem has been its association with the OAS. The programme was developed through political actions and it has never lost that association in the eyes of its critics. The United States' dominance

Bolivian reactor project

of the OAS and its manipulation of the region to secure hemispheric solidarity has raised many doubts about the worth of any OAS programme.

Undoubtedly, the benefits have not been as large as they might have been. The more developed countries have benefited most from the programme, but this should be expected since they have a better science and technology infrastructure. The Mar del Plata account has helped to redress the balance, but the main issue here is that it limits the amount of money countries can obtain. The newly created Simon Bolivar fund, financed mainly by Venezuelan petrodollars, will concentrate its efforts on rural development—PRDCYT's main problem is that it has not been closely linked to direct economic development. Criticisms of it on technology transfer conditions, patent legislation and types of development, however, are spurious, since these are issues that have to be settled internally by national policies. Awareness of these problems on the part of some national agencies has actually stemmed partly from PRDCYT-organised courses, but these agencies find it difficult to convince their superiors of the need for integrated science policies.

PRDCYT has been important in the development of the scientific and technological infrastructure of the Latin American nations. Through its efforts many centres of excellence now exist that are the prerequisites for the generation of indigenous technology. Many institutions rely on the programme for financial support for research, since they receive very little money directly from their own governments. According to Article 45 of the OAS Charter, governments should encourage science that is oriented toward the overall improvement of the individual—that is a foundation for democracy, social justice and progress. In too many Latin American countries money is used for the very opposite purposes. □

Danger: men at work

Judy Redfearn looks at the problems facing those concerned with major hazards in Britain

ALMOST three years ago an explosion at a Nypco factory in Flixborough killed 28 people and injured more than 100. It shocked the British public into awareness of the possibility of other major industrial accidents. The Health and Safety Commission's Advisory Committee on Major Hazards was set up in the wake of Flixborough to lay down recommendations for the control and supervision of major hazards. Nine months ago it published its first report, which helped those concerned with industrial safety to think seriously about its recommendations and how to implement them. Some of the problems that report brought to light have since been discussed, notably at a meeting organised by the Institution of Mechanical Engineers at the beginning of May, when representatives from industry, local authorities, the Health and Safety Executive (HSE) and the committee itself got together in London.

The report's main recommendation poses a major problem. The recommendation was that a 'notification' scheme should be set up to help the HSE compile a list of major hazards: all installations would be subject to review, even though most would demand no more regulation than already exists under the 1974 Health and Safety at Work Act; but potentially hazardous installations would be required to submit a detailed survey of their activities to the HSE. At the moment, this is voluntary, but the committee would like to see it enforced by legislation.

The problem with the scheme is the burden it will impose on the HSE. Not only will the Executive receive a large number of surveys from all kinds of installations; it will also need to examine in great depth those which might indicate a major hazard. To relieve some of this burden, the committee has suggested that individual companies should be responsible for indicating their own problems and outlining the solutions. But this still means the HSE will need more specialised staff. The committee has suggested that outside expertise should be made available at any time.

Another difficulty is that it is not yet clear how the top league of hazardous installations would be controlled: whether by regulation or licensing. The committee feels that it can only wait until both local authorities and the HSE have acquired, under the notification scheme, fairly comprehensive in-

formation on the types of activity they will be controlling and on the problems they will be facing before it can recommend which way to go. One of the dangers it wishes to avoid is transferring liability for major accidents from industry to the regulating body. Whatever machinery is set up, some industrialists feel that a major stumbling block will come in trying to ensure that their special case is understood by whoever is to judge it. And in the end what does or does not constitute a major hazard will be someone's subjective judgment.

Nor is this all. Accidents happen—either through the fault of people operating machinery or through mechanical breakdown—but the extent of the damage they cause depends on environmental factors. The report recommended that new plants should be planned to take account of the likely consequences of a major accident: buildings should be capable of withstanding shock from explosions and of containing toxic chemical leaks and should be situated away from densely populated areas. Machinery should be designed to the highest specifications and staff should be continually retrained in operating procedures.

The trouble is, human error can never be eliminated, whether in the

design or in the operation of an industrial plant. The recent meeting produced a general call for more research into the relative safety of automatic control systems and human control: it was asked, for example, whether it was safer to leave everything to machines and to have no one about when an accident does happen, or to have somebody there to warn others when something goes wrong. The committee is also concerned about the lack of knowledge on the massive release of toxic and flammable gases that are heavier or lighter than air.

Industry expects other problems once a plant has been labelled a 'notifiable installation'. For example, people have to be convinced that it is safe to work there. The feeling is that if a reputation has been established for giving reliable information on all aspects of its work, employees are likely to trust what is said about safety. The difficulty is that too often in the past industries have been found to have wrong statistics even on fundamental points. Public confidence will only be inspired if industries are seen to be reliable. A possible way of educating the public might be through the unions, but they have yet to be approached.

The committee's work is still in its first stages. It plans to hear more evidence and produce other reports as and when it sees fit. It still has many points to clarify before it can recommend further action and through the HSE it is liaising with the Dutch—the only other nation looking into major hazards. In the meantime it is simply waiting to see what turns up. □

Devastation at Flixborough

ITALY

Distant drums

The pollution threat posed by the cargo of a submerged ship in the Adriatic could now be receding. Alastair Hay, recently in Italy, reports

FOLLOWING a collision with a Panamanian ship in July 1974, the Yugoslav vessel *Cavtat* sank three and a half miles off the coast of Otranto, in southern Italy. The *Cavtat* was carrying as part of its cargo 270 tons of the petrol 'anti-knock' additives lead tetraethyl and lead tetramethyl. These were stored in drums and located in the hold and on the deck. Three years later, most of the drums are still there—under three hundred feet of water at the entrance to the Adriatic.

The pollution problems of the Mediterranean are legion. Those of the Adriatic are even more numerous. Industrial effluent discharged directly into the Adriatic without prior processing has led to an increasing accumulation of heavy metals, particularly of lead, zinc, cadmium and mercury. The Italian government has taken steps to control the discharge of untreated effluent. However, equal concern was not at first in evidence for the pollution threat posed by the leakage from the drums in the *Cavtat's* cargo. Indeed, it took the government more than two and a half years to act: on 3 February this year, following a midnight cabinet meeting, the government finally announced that £6.7 million was being set aside over a two-year period for salvage operations to raise the drums.

Several factors forced the government to take this decision: a growing realisation that the cargo, if left undisturbed beyond the spring of this year, will be impossible to salvage; publicity about the pollution hazard which is having a serious effect on the local tourist and fishing industries; and a vocal Otranto magistrate, Alberto Maritati. Shortly after the accident,

Maritati began an investigation and sought scientific advice on the hazards posed by the lead compounds. Most scientists agreed that, if the chemicals were to escape from their drums, a major ecological disaster could well ensue. But opinion differed as to the advisability of raising the drums to the surface. Some considered that the drums were better left on the sea bed and perhaps carpeted with a layer of concrete. The British firm of Octel, who manufactured and packed the lead products, considered the *Cavtat* problem to be a storm in a teacup, the company's technical manager reportedly having said that "... the best thing to do is to leave the drums down here. If it was all released at once, it wouldn't cause much of a problem in my opinion. I think it is an exercise in sheer futility".

This, however, has not been the majority view of the problem. Reports from marine scientists and toxicologists confirmed Maritati in his opinion that the lead compounds were hazardous and could enter the marine food chain. He attempted to obtain government support for his decision to raise the *Cavtat's* lethal cargo. Despite dozens of journeys to Rome and many formal written requests for assistance he received little support for his project. Maritati had powers invested in him as a magistrate to initiate the salvage programme, but he had no funds to pay for it. This was the government assistance he sought. Finally, on 26 January, and still without the promise of government aid, Maritati issued an order requiring the Saipem company—experts in underwater engineering, and a subsidiary of the Italian state oil company, ENI—to begin salvage operations. The magistrate was convinced of the need for urgency after the inspection of a drum raised in December by a team of divers had revealed corrosion of the containers and confirmed their porosity; it seemed essential that all the drums be brought to the surface before further corrosion made the operation too hazardous.

Interviewed recently, Maritati told *Nature* that he required no additional assistance from the central government. A Communist Party member dealing with Christian Democrats, he said his efforts to enlist government support had resulted in an assurance that it would pay for the entire salvage operation. He was told that there is now an arrangement between the Department of the Merchant Navy and

Poisoned fish caught in the Gulf of Taranto

Saipem "that all the drums will be raised". Saipem is working with the manufacturers Octel, who will handle the drums when they are brought to the surface.

The most difficult part of the salvage process will be to secure the drums in the ship's hold. However, Saipem are convinced that the problem is not insuperable and have assured Maritati of this fact. Maritati says that it is "a problem which requires urgent attention. I visit the site every day to ensure that the operation is proceeding to my satisfaction. There should be no interruptions in the salvage operation. This being so, all the drums will be raised by June. And so tourists will have nothing to fear".

Once the cargo is neutralised the *Cavtat* problem will still feature prominently in the courts. The captain faces criminal prosecution on two counts: that of polluting territorial waters, and of criminal negligence—he is alleged to have refused the help of Italian tugs which could have towed his ship to safety. Maritati will be involved in this legal process, but for the moment he has won his case for government assistance. The government, too, is anxious to bring the matter to a speedy conclusion. Officials in the Ministry of Foreign Affairs were insistent that central government hesitation on the issue was not due to any deliberate obstruction, but to the fact that so many departments were involved in the affair; consultation with and between all the departments was essential before any action could be taken. That action is finally in view. Everyone hopes that the outcome will be a potentially cleaner Adriatic. □

USA

●A key advisory committee last week decided to recommend that guidelines which now govern recombinant DNA experiments in the United States should be amended to facilitate experiments with human DNA. Though the committee's recommendation, which will eventually be made to the Director of the National Institutes of Health (NIH), may not be accepted, it is sure to generate considerable debate.

The committee, the Recombinant DNA Advisory Committee, carries considerable weight because it was largely responsible for drafting the present NIH guidelines. The guidelines require that recombinant DNA experiments involving human genes must be performed in the highest level of physical containment (P4), and in addition, crippled strains of micro-organisms must be used (a so-called EK2 system). Those requirements effectively bar work with human genes for the time being because no P4 laboratories have yet been certified, and few universities are likely to build them. The advisory committee will recommend, however, that the containment level should be reduced to P3 and EK2, a level which would allow such work to go ahead in many places.

The committee decided to recommend the change for a variety of reasons, and its vote was 11 to 1, with one abstention. A number of committee members told *Nature* last week that they agreed to recommend the change because they feel that evidence, accumulated since the original guidelines were drafted, indicates that potential hazards associated with many types of recombinant DNA research are extremely remote, and work with human DNA is likely to yield important results. In particular, Roy Curtiss of the University of Alabama, who proposed the change, argued that so far nobody has found faithful expression of vertebrate DNA in *E. coli*, that if cloned DNA were to get into the intestine it would rapidly be degraded by enzymes in the gut, and that several experiments suggest that *E. coli* containing 'foreign' genes is at a selective disadvantage.

The move is sure to be criticised on scientific as well as political grounds, however. Experiments involving human DNA were assigned to the highest level of physical containment largely because of the possibility that human cells may harbour cancer viruses whose genes might be picked up and cloned along with the human DNA, but some of the advisory committee members noted that so far an

intensive search for human cancer viruses has failed to find any. That potential hazard cannot be entirely ruled out however, and the recommended relaxation of the guidelines is therefore likely to be controversial.

The committee will meet again in June to discuss further recommendations to amend the guidelines, and its proposals will eventually be sent to

the NIH Director Donald Fredrickson, who will almost certainly subject them to public discussion before acting upon them. In the meantime, Congress is busy working on legislation to regulate recombinant DNA experiments, and it is likely to require that new regulations be drafted. It could take as long as 18 months for new regulations to be drafted and implemented, however, so the NIH guidelines are likely to be important for some time yet.

●Meanwhile, in a move which is sending a few tremors through the biomedical research community, the environmentalist organisation Friends of the Earth, has gone to court to seek an order halting federal funding of recombinant DNA research in the United States. The organisation has charged that NIH violated the law by failing to publish an environmental impact statement before it issued its recombinant DNA guidelines last year.

The law in question, the National Environmental Policy Act, requires that government actions likely to affect the environment must be preceded by publication of an analysis setting out the potential environmental impact and discussing alternative courses of action. NIH issued its recombinant DNA guidelines in July, and it published a draft environmental impact statement six weeks later. A final version of the statement is now

under review in the Department of Health, Education and Welfare and it has yet to be published.

The chief reason why the process got out of step was that NIH didn't realise until the guidelines were in the final stages of being drafted that an environmental impact statement would be required. A long delay in issuing the guidelines would therefore have resulted if NIH had followed the letter of the law.

When the draft environmental impact statement was published in August, NIH Director Donald Fredrickson admitted that the legal process had been short-circuited, but he argued that the public interest was best served by prompt issuance of the guidelines. Recombinant DNA experiments were then proceeding under general safety rules recommended by a group of geneticists which met at Asilomar, California, early in 1975, and since the NIH guidelines are more strict than the Asilomar rules, Fredrickson argued that "the escape of potentially hazardous organisms was more likely in the absence of NIH action".

Friends of the Earth is claiming that because NIH failed to follow the procedures laid down by the National Environmental Policy Act, the guidelines were issued improperly and should be withdrawn. Federal funding for recombinant DNA experiments should then be halted, the suit demands, pending the resolution of safety issues.

NIH has 60 days to respond to the suit, and lawyers from the Department of Health, Education and Welfare met last week to discuss their response. Even if the courts find that NIH violated the letter of the law, however, they need not necessarily require a halt to the research.

●A bill to provide a major infusion of funds into earthquake prediction and into the design and construction of earthquake resistant buildings, dams and other structures, was approved unanimously by the Senate last week, and it has also been passed by a key committee in the House. The bill, which has been kicking around Capitol Hill for several years, is thus virtually certain to clear Congress in the next few weeks. It would authorise expenditure of \$55 million next fiscal year and a total of \$205 million over the next three years for earthquake research, and it directs the President to draft an implementation plan and to recommend ways to help communities prepare for earthquake warnings.

Colin Norman

COMECON

Space relations

The Comecon countries' joint space programme includes a manned mission planned for next year. Vera Rich describes preparations

THIS year, which marks the twentieth anniversary of the first Soviet satellite Sputnik 1, is also the tenth anniversary of the joint Comecon 'Interkosmos' programme. To date, the achievements of Interkosmos have amounted to the launching of 16 orbital probes and four high-altitude rockets. Last year, however, a major new development was announced: the Soviet manned space programme would be extended to include cosmonauts from the other member countries of Comecon.

The first trainees, said to be from Poland, East Germany, and Czechoslovakia, arrived early this year at the 'Star City' training centre near Baikonur, and candidates from other Comecon countries are joining them during the course of the year. As the first manned Interkosmos mission is planned for 1978, the training programme is clearly a considerably abridged version of the normal Soviet five-year course, and it is therefore not surprising that from the start it has been stressed that each joint mission will be captained by a Soviet cosmonaut.

The prospect of a fellow-citizen in orbit has done much to rekindle interest in space research throughout the Comecon bloc. A recent exhibition in Warsaw of Soviet scientific achievements included a special 'Kosmos-77' pavilion which, in the course of five weeks, attracted more than 1.2 million visitors. The Soviet 'Cosmonautics Day' festival—the anniversary of Gagarin's flight—fell during this exhibition and was celebrated with fitting honours, including a visit from Professor Roald Z. Sagadiev, Director of the Institute of Space Research of the Academy of Sciences of the USSR, and cosmonaut-pilot Viktor V. Gorbachko, captain of the recent Soyuz 24 mission.

The participation in the not-too-distant future of a Polish cosmonaut in a joint mission might well have been expected to form a major theme of the speeches on this occasion. However, Professor Stefan Piotrowski, Head of the Committee for the Investigation and Peaceful Uses of Space of the Polish Academy of Science, chose to concentrate on the special 'Kopernik 500' Interkosmos launch of April 1973, "the most important Polish space experiment to date", for which, in

honour of the Copernicus quincentenary, "almost all the apparatus and scientific programme" was produced by a Polish team. From the Soviet side, Professor Sagadiev spoke largely of such future prospects as deep-space probes to the outer regions of the solar system, orbital laboratories, and satellite monitoring of weather, crop prospects and pollution. The proposed launching order of the Comecon cosmonauts remains a closely guarded secret.

This is, of course, in accordance with Soviet practice which normally never permits the disclosure of details of a mission in advance. There is undoubtedly unofficial rivalry between the Comecon countries as to whose cosmonaut will blast off first, and a minor set-back in training or a last-minute indisposition leading to a change in order might lead to undesirable tensions and ill-feeling between the countries concerned.

It is noteworthy, however, that the three countries whose representatives arrived first at the training centre are those which have been most closely concerned with the unmanned Interkosmos probes, providing instrumentation and experiments for the satellites. East Germany, in fact, not only supplies electronics and telemetry systems for the Interkosmos satellites, but also in September 1976 provided a special 'multispectrum' camera for the Soviet Soyuz 22 mission.

The final goal of the Comecon bloc is total economic integration, and although the current five-year plans are temporarily playing down this aim, concentrating rather on a short-term (15–20 years) drive towards integration in certain significant areas, one of these chosen fields is instrumentation. The selection of East German, Czechoslovak or Polish equipment for Interkosmos satellites is an outcome of this policy. Since, under the complicated financial arrangements involved, it is the supplying countries who pay for the R&D, the planners might feel that priority given to the cosmonauts from these countries would be a graceful compliment to their considerable effort and outlay. It would also be a way of stilling the rumours of discontent that the other Comecon members are paying the lion's share of grandiose projects initiated by the Soviet Union and for which the Soviet Union gains the acclaim.

It should be remembered, however, that in spite of special satellite tracking ships, the Soviet Union relies heavily on ground bases in the Come-

con countries. Because of their geographical location the two least-developed members—Cuba and Mongolia—are particularly important in this respect; indeed, Cuba joined the Comecon 'Intersputnik' communications systems when the latter was first set up in November 1971, eight months before becoming a member of Comecon itself. Under the Intersputnik agreement ground stations are owned and operated by the countries in which they are sited. Although as developing countries Mongolia and Cuba are said to receive the necessary Intersputnik facilities from the Soviet Union free of charge (unlike the European members of Comecon which must bear the cost themselves), the value of the Havana and Ulan-Bator tracking bases to the Soviet space programme is not expressible in roubles, and the inclusion of Cuban and Mongolian cosmonauts in the training programme reflects a genuine contribution made by these countries and is not simply a tribute to the principle of the 'friendship of nations'.

Although the joint teams of the Interkosmos manned missions will presumably carry out the now routine geophysical and astrophysical observations, medical checks and, possibly, experiments on the effect of weightlessness on physical and chemical processes such as crystal growth, it seems unlikely that the non-Soviet cosmonauts will contribute any special knowledge or expertise which their Soviet counterparts could not have provided. Rather is it a grand exercise in public relations, to demonstrate the fraternal cooperation of the Socialist countries—and to provide for those countries a greater involvement in the Interkosmos programme than equipment on board a Soviet-built satellite or a tracking station on their soil. □

Inspecting Interkosmos 10

UK response

foreign uranium supplies, uranium enrichment as a source of weapons, development of international reprocessing facilities and storage of unprocessed fuel, he was apparently serving notice that the political battle to win a consensus could be drawn out.

UKAEA plans

Apparently in response to fears expressed by critics of nuclear power over the threat of plutonium diversion, the UK Atomic Energy Authority (UKAEA) is planning to demonstrate two methods of combating the problem. Speaking last week, the UKAEA chairman, Sir John Hill, said that the UKAEA was proposing to build a

finement. *Aviation Week* cites the revelations by the Soviet physicist Leonid Rudakov last summer during a tour of US fusion laboratories. Rudakov, "in response to a taunt by a western scientist", revealed that

[illegible]

The test site that is crucial to General Keegan's thesis is at Semipalatinsk near the Tibetan border. *Aviation Week* describes in detail a large building containing two steel spheres and states that since November 1975 seven tests "that may be related to development of a charged-particle beam device" have been carried out. The only evidence for the tests cited, however, is the hydrogen with traces of tritium in the upper atmosphere—which could mean almost anything.

According to *Aviation Week* the Russians have made advances in explosive or pulsed power generation, flux compression, pressurised and cryogenically cooled power cabling, very large capacitor construction, energy switching, electron injection and collective acceleration. Together these advances would give them the ability to produce a proton beam intense enough to be used as a weapon. It is claimed that for some of those technologies the Russians are farther advanced than the Americans; in others General Keegan says the Russians have access to US advances which they were previously believed not to know about.

"the USSR can convert electron beam energy to compress fusible material to release maximum fusion energy".

But this is far from the description of the event given by other high energy physicists, who say that Rudakov merely gave technical details (which happened to be classified in the US at that time—hence the fuss) of a Russian experiment that had been widely reported in the West several months earlier. True, in that experiment the Russians had for the first time produced some neutrons in an attempt at electron beam fusion, an achievement that the Americans have not yet matched. It is doubtful that Rudakov blurted out his secrets by accident; he stood to gain much more in international prestige than he lost by indiscretion. For the same reason high energy physicists believe that, as the Russians

Another aspect of the technology *Aviation Week* touches on is accelerator design. For a land-based beam there is the perhaps insurmountable problem of propagation through the atmosphere without losing all its energy. A satellite-based beam is therefore an attractive proposition but would limit the size of the extremely powerful accelerator that would have to be carried on board. Theoretically there are several ways of decreasing the size of an accelerator; they include the idea (originating in the Soviet Union) of a collective accelerator in which the protons that will form the beam are initially surrounded by electrons which drag them along and are more easily accelerated; the electrons are then blown off to leave the beam.

This concept has received considerable attention both in the Soviet Union and in the United States but has now been largely discarded. The 'smoke ring' collective accelerator experiments at Berkeley, for example, have stopped because of enormous problems in creating a stable, sufficiently intense electron beam. Interestingly, *Aviation Week* fails to discuss any evidence of Soviet progress in that area. It seems therefore that at least one crucial component of a satellite-based beam weapon is not yet technologically feasible.

Even if General Keegan's assessment of Soviet technology in most areas is substantially right, there remains the claim of whether the ultimate aim is a beam weapon. The interesting thing about *Aviation Week's* list of technologies is that they are all equally crucial for the development of fusion by an electron or laser beam. The location that General Keegan interprets as a beam weapon test site is equally likely to be used for fusion experiments. And being first with fusion would confer a good deal more power than ownership of a decidedly cumbersome and delicate weapon.

fuel fabrication plant at Dounreay, now the site of Britain's 250 MW prototype fast reactor and of a fuel reprocessing plant. This would eliminate the need to transport plutonium once the initial charge is delivered.

The UKAEA also hopes to demonstrate the concept of a single reprocessing plant servicing a "substantial number" of reactors. The idea of irradiating reprocessed and refrabricated fuel before it is dispatched back to a reactor is apparently under consideration, but there may, according to Sir John, "be easier, more convenient ways of achieving the same objective developed in the interim".

Convention signed

Representatives of over thirty countries, including the United States and the Soviet Union, gathered in Geneva last week to sign an international convention known as Enmod which prohibits the hostile use of environmental modification techniques. The convention, which took three years to negotiate, allows research and develop-

ment on the manipulation of the environment for peaceful purposes.

ACOPS report

A 20% increase (500 to 595) in the number of pollution incidents around UK coasts between 1975 and 1976 is reported in the annual report of the UK Advisory Committee on Oil Pollution of the Sea. The report, out last weekend, expresses disappointment at the lack of progress at the UN Law of the Sea Conference, another session of which opened this week in New York.

More teaching companies

To improve the interaction between industry and universities, the UK Science Research Council (SRC) and the Department of Industry (DoI) have agreed to expand the Teaching Company Scheme over the next five years. They will share the cost equally and have made provision for a maximum of £2 million to be spent in any one year.

First proposed in 1975, the scheme was designed to introduce able grad-

uates to industry under the joint super-industrial workers, in the hope that vision of university academics and they would remain and follow careers in management. Initially, the scheme was taken up by five companies in cooperation with nearby universities and although these programmes have suffered problems it has been decided to go ahead with new ones. Two more schemes were approved last week: Lesney Products in cooperation with North East London Polytechnic, and Anderson Strathclyde Ltd in cooperation with the University of Strathclyde. The target is now twenty teaching companies by 1982.

Asbestos meetings

The UK Advisory Committee on Asbestos, set up in March last year by the Health and Safety Commission to review the risks to health from exposure to asbestos, has invited individuals and organisations who have submitted written evidence to attend three public meetings the committee is holding in London next month.

THE world's oil deposits are finite, and are likely to be exhausted within the next hundred years. Pessimists suggest that they may only last for twenty-five years, optimists believe there are supplies for two or three times as long. In the past oil has caused a great deal of environmental damage, including air pollution from refineries and spills from wrecked tankers such as the *Torrey Canyon*. The recent blowout at the Ekofisk rig in the North Sea is a reminder of continuing dangers which are unavoidable. It is important to ensure that this short-lived, though important, industry does not leave behind a permanently damaged world.

Although the oil industry exists to make a profit, the major companies have for some years taken a responsible attitude to the environment. A recent manifestation of this is the establishment of the Conoco Lecture by the Continental Oil Company, one of the major international entrepreneurs in this field. The first lecture was by Dr Peter Chapman, of the Energy Research Group of the Open University, on "The responsibility of industry towards the environment". He demonstrated how important it was to consider all stages in, for instance, energy generation, when trying to reduce pollution. A comparatively clean power station might depend on fuels and machinery which had already produced massive pollution. He stressed the point that

'market forces' themselves could not be relied on to protect the environment, and that industry must be prepared to accept restraints which may

Duty on oil

KENNETH MELLANBY

reduce its profitability.

Pollution control is very complicated, and few generalisations can be widely applied. Legislation may or may not be effective. The first British Alkali Act of 1867 was strongly resisted by industry, but was effective in reducing the serious damage done by hydrochloric acid from alkali works. The Clean Air Act of 1965 is generally given the credit for clean-

ing the air of London and other cities; this myth was again propounded by Dr Chapman. Actually the amount of smoke and dirt in the air in Britain had been falling rapidly for ten years before 1956, and the rate of decrease was actually slower, not faster, after the Act was passed. It would be an abuse of the statistics to suggest that this law actually prevented air pollution from being controlled, but the main causes of the improvement were economic. By 1956 much of industry had already changed from burning raw coal to using oil, gas or electricity, all cleaner (and, at the time, cheaper) fuels. The change in domestic heating had been slower, but in more prosperous areas clean methods of central heating were widely used when the Act came into force.

Since 1956 it has been possible for local authorities to declare 'smokeless zones' where the domestic use of raw coal is forbidden. This has undoubtedly made the final clean-up of such areas possible, but smoke continues to pour out of the chimneys of many houses in our poorer areas, or in those where our miners receive—and burn—over ten tons each of concessionary coal a year. The law has been much less effective than have economic forces in cleaning Britain's air. It will be interesting to see the effects on the environment of the proposed expansion of our coal industry.

correspondence

Separating swimmers

SIR,—Within the past few years the electronic timer, capable of responding to time differences of .001s, has replaced the stop-watch, capable of responding to time differences of perhaps .05s. In world class swimming events are now decided and records are established by amounts down to .01s. Detailed regulations for the use of such devices are given in the handbook of the international swimming federation FINA. A recent modification to these regulations, passed at the Montreal Olympic Congress in 1976, prohibits the separation, even for placing, of swimmers by times less than .01s. Clearly, the significance of such accurate timing needs examination.

According to FINA Regulation, a pool for an Olympic or for a World Games must have a length of 50.00 m with a "tolerance of ± 0.03 m". In other words, the maximum permissible error in length, from one pool to another, is $\pm 0.06\%$. This error is recurrent and will remain the same, no matter how many lengths of the pool are swum. If timing is conducted to one-hundredth of a second electronically, that is to ± 0.01 s, the maximum possible timing error in the fastest event, the Men's 100 m Freestyle swum in a typical time of 50s, is 0.02% . The timing error of 0.01s is not recurrent, and so the percentage timing error decreases for longer distance races, taking longer times.

It is well known that the overall accuracy of any measurement is set by the least accurate measurement. For the example above, the Men's 100 m Freestyle, the maximum possible error, 0.06% , is three times the maximum possible timing error of 0.02% , the ratio becoming more unfavourable for longer distances.

It is therefore not valid to compare records made in different pools, unless the times can be corrected to the exact length of the pool, or unless the time difference is, in the case of the Men's 100 m Freestyle, at least 0.03s and correspondingly greater for longer distances up to a maximum of about 0.5s for the Men's 1,500 m swum in a typical time of about 15 minutes. Current listings of world records do not appear to make this distinction, and there is no indication that the records have been corrected to the appropriate pool length. Although in practice many records are established by better

margins, in some cases, especially over shorter distances, 0.01s separation has been the deciding factor.

The figures quoted are typical and not, of course, exact. This does not alter the argument or the general conclusion, however. As surveyor's measurements are usually more accurate than the FINA tolerance of $\pm 0.06\%$, it might be better to specify all records after correction to the 'exact' (that is, the surveyor's) pool length, rather than to attempt to define separation times for each event and every pair of pools. The correction could be programmed into the electronic timer itself. In fact, it is the velocity of the swimmer that is really of interest. Time is used as a convenient indicator, but the assumption is implicit that all course lengths are all known exactly to be equal. Similar arguments may apply in other sports.

Other points might also be mentioned:

- If all the lanes in a given pool are known to be of equal length it may be valid to *separate* swimmers to 0.01s accuracy.

- The well-known problem of the velocity of the sound of the starter's gun is accounted for by separate horns, one at each starting block, each linked to the timer and to the starter's gun. If this is not done, the swimmer in the farthest lane from the gun will start with a disadvantage of some 0.03 to 0.06s, depending on the pool width and the position of the starter along the side of the pool.

- Expansion of the pool with changing water temperature has sometimes been cited as another possible source of error. Water temperature must be maintained at a minimum of 77°F and is unlikely to exceed this by more than a few degrees. For typical materials and temperature ranges the effect of expansion is about an order of magnitude smaller than the pool length tolerance and is not, therefore, significant.

Carcinogens and cancerogens

SIR,—The amusing exchange between Lijinsky and Jukes (7 April, page 494) appeared even more droll because they both used the term carcinogen in such a way as to leave question to their

meaning. 'Carcinogen' should refer to the production of carcinomas, that is, tumors of epithelium. Agents that produce sarcomas, leukemias or other neoplasia as well as carcinomas should properly be called cancerogens. I doubt that either correspondent intended to limit their meaning to substances producing only carcinomas—they have followed a widespread but incorrect usage.

Inexhaustible energy

SIR,—J. Tuzo Wilson (20 January, page 196) has argued that economics must change because the era of cheap energy is past. Many scientists have claimed that the watchword of the next era will be inexhaustible energy. R. W. Cahn (10 March, page 106) has given reasons why fusion power does not really meet this description.

A current campaign, in the United States at least, is to build solar energy collectors in space, and beam energy to the Earth's surface. It is said these would last as long as the Sun does. I feel there must be some flaw in this "inexhaustible energy source" too, and wish someone would tell me what it is.

Photosynthesis and photorespiration

from A. L. Moore

DURING photosynthesis, many plants release previously-fixed CO_2 in a light-dependent oxidation process known as photorespiration. The process occurs chiefly in higher plants which fix CO_2 exclusively by way of the C_3 pathway of photosynthesis (the Calvin Cycle). The role of photorespiration is obscure and it is frequently regarded simply as a wasteful process; it has been proposed that net CO_2 fixation by photosynthesis could be increased by up to 50% by preventing photorespiration and the associated oxygen inhibition of photosynthesis. Since all major crop species except maize, sorghum and sugar cane actively photorespire, a major opportunity to increase crop productivity may lie in the control of photorespiration (see Zelitch *Nature* 256, 90; 1975; Chollet & Ogren *Bot. Rev.* 41, 137; 1975), and recent work by Bolhar-Nordenkamp (*Biochem. Physiol. Pflanzen* 169, 121; 1976) aimed at disentangling the complex effects of various environ-

mental factors on the rate of photorespiration and photosynthesis may be an important step towards this goal.

Factors affecting photorespiration include light, high levels of O_2 or low levels of CO_2 in the atmosphere and high temperature. Increases in temperature differentially increase the rate of photorespiration with respect to photosynthesis, whereas photorespiration increases proportionally to photosynthesis as light intensity increases. Bolhar-Nordenkamp has described the interaction of these factors as they affect the conditions necessary for optimal photosynthesis. Figures 1 and 2 show that the greatest light efficiency for optimal CO_2 fixation (CO_2 fixed per given amount of light) occurs at low light intensities, high CO_2 tensions and temperatures near 35°C ; but at atmospheric CO_2 tension (150–400 p.p.m.) the optimum temperature is near 25°C (Fig. 2). However, photorespiration is optimal at high light intensities, high temperatures and low CO_2 tensions. The amount of CO_2 (p.p.m.) in the atmosphere that can be used by the leaf to produce

1 mg CO_2 fixed per g dry weight per h (p.p.m. mg^{-1} in Figs 1 and 2) is optimal between 100 and 650 p.p.m. CO_2 at all light intensities (Fig. 1) and between 150 and 1,000 p.p.m. CO_2 at all temperatures studied (Fig. 2). Similarly CO_2 "fertilisation", which is the proportion of added CO_2 fixed for a given amount of CO_2 in the atmosphere ($\Delta\text{mg}/\Delta\text{p.p.m.}$, Figs 1 and 2), is optimal in the range between 150 and 400 p.p.m. CO_2 at high light intensities (Fig. 1) and high temperatures (Fig. 2). Figure 3 depicts the points of optimal use of light intensity and CO_2 tension for maximal photosynthesis. From Fig. 3 it may be noted that below light intensities of $0.02 \text{ cal cm}^{-2} \text{ min}^{-1}$ and 150 p.p.m. CO_2 concentration, there is no net photosynthesis. This implies that an increase in net photosynthesis can only be achieved by increasing both these factors above the minimal levels. It is also apparent from Fig. 3 that at any given temperature (15°C for example) any variation in either atmospheric CO_2 or light intensity (within the hatched area) will result in the same net photosynthesis. For example at 25°C at light intensities of $0.15 \text{ cal cm}^{-2} \text{ min}^{-1}$, varying the CO_2 concentration between 250 and 1,000 p.p.m. has no effect on net photosynthesis. Similarly at 300 p.p.m. CO_2 and at 25°C , varying the light intensity between 0.05 and $0.16 \text{ cal cm}^{-2} \text{ min}^{-1}$ has no effect on net photosynthesis. But by increasing the light intensity over the range 0.08 to $0.34 \text{ cal cm}^{-2} \text{ min}^{-1}$ and CO_2 concentration over the range 300 to 1,500 p.p.m. at 25°C it is possible to increase net photosynthesis from 25 to 100 mg CO_2 g dry weight per h. Thus only by CO_2 enrichment and high light intensities is it possible to counteract the depression of C_3 net photosynthesis that normally occurs at 35°C .

It is of practical importance that CO_2 enrichment has the added advantage of not only decreasing photorespiration but also increasing nitrogen fixation by symbiotic bacteria in root nodules. It has been suggested that the amount of photosynthate available to the nodule may be the primary factor for limiting nitrogen fixation, and any conditions that increase available photosynthate to the bacteria in the roots would increase nitrogen fixation.

High light intensities in combination

Fig. 1 Effect of CO_2 concentration at four light intensities ($\circ$, 0.556; $\bullet$, 0.265; $\blacksquare$, 0.150; $\blacktriangle$, 0.065 $\text{cal cm}^{-2} \text{ min}^{-1}$) on net photosynthesis at 25°C . —, % light efficiency, ϵ (CO_2 fixed per given amount of light); —, "CO₂ fertilisation" ($\Delta\text{mg}/\Delta\text{p.p.m.}$); , CO_2 in atmosphere used to fix 1 mg CO_2 per g dry weight per h (p.p.m./mg). CO_2 concentration is given in p.p.m. on a log scale.

with atmospheric O_2 pressures (high) and CO_2 tension (low), result in the production of oxygen free radicals during the normal photosynthetic electron transport processes. Bolhar-Nordenkamp suggests that photorespiration occurs as a result of the overproduction of oxygen radicals and the function of photorespiration is thus to prevent any photo-oxidation reactions which could otherwise easily damage the cell. This is thought to be by way of an interaction with glycolic acid metabolism. The mechanism of photorespiration is still controversial, but it is believed that the metabolism of glycolate which may be derived from one or more intermediates of the C_3 pathway, is intimately involved.

Several reactions have been proposed to account for the CO_2 release from glycolate. It is generally accepted that glycolate is oxidised to glyoxylate by glycolate oxidase in the peroxisomes; the glyoxylate is then transaminated to glycine. Glycine is transported out of the peroxisomes into mitochondria where it is converted to serine and CO_2 ; this step is possibly associated with some degree of energy conservation. Recent results in fact show that intact spinach leaf mitochondria can oxidise glycine with good respiratory control and its oxidation is coupled to three phosphorylation sites. The conversion of glycine to serine is currently considered to be the major reaction releasing CO_2 during photorespiration at temperatures up to $25^\circ C$. An alternative reaction leading to the evolution of photorespiratory CO_2 is the direct decarboxylation of glyoxylate to formate, in both peroxisomes and chloroplasts, by a non-enzymatic reaction with H_2O_2 . It is thought unlikely, however,

Fig. 2 The effect of CO_2 concentration at three temperatures ($\blacktriangle$, $15^\circ C$; $\blacksquare$, $25^\circ C$; $\bullet$, $35^\circ C$) on net photosynthesis at a fixed light intensity ($0.15 \text{ cal cm}^{-2} \text{ min}^{-1}$). Other symbols as in Fig. 1.

that this non-enzymatic decarboxylation in peroxisomes contributes more than 10–20% of the CO_2 released during photorespiration (see Halliwell *New Phytol.* 73, 1075; 1974).

The superoxide free radical anion (O_2^-) (produced by the reduction of O_2 in a one-electron step) may also play an important part in photorespiration. Although there is sufficient catalase present in the peroxisomes to destroy 80% or more of the H_2O_2 generated during glycolate oxidation, mitochondrial fractions from spinach leaves and purified

mitochondria from some etiolated tissues have been shown to generate H_2O_2 *in vitro*. The production of H_2O_2 by isolated chloroplasts is a well known phenomenon. Superoxide dismutases which catalyse the breakdown of O_2^- to O_2 and H_2O_2 have been found in the chloroplasts and mitochondria of spinach leaves. Since both mitochondria and chloroplasts contain systems which can generate O_2^- , it is likely that superoxide dismutases function to remove it. Their significance in relation to CO_2 release in photorespiration is, however, still to be evaluated. $\square$

Growth hormones and serum factors

from Robert Shields

It has been apparent for some time that only around 10% of the insulin-like activity in serum can be suppressed by insulin antibodies, but only now has the nature of the rest of the activity become clearer. Recent reports show that this non-suppressible insulin-like activity (NSILA) is due to a peptide structurally related to insulin, and that this peptide is probably the major growth hormone in the body as well as being a "serum factor" for *in vitro* cell culture.

Attempts to purify NSILA have been hampered by the fact that no organ seems to have high levels of

Robert Shields is a research fellow at the Imperial Cancer Research Fund, London.

activity and the concentration of the protein in plasma is very low. Industrial scale procedures are needed to isolate only a few milligrams of material from several tons of human plasma. The usual purification procedure begins with the fractionation of plasma by the Cohn procedure (essentially a series of controlled ethanol precipitations under increasingly acid conditions). Acid/ethanol precipitation of the Cohn IV precipitate (weighing a few kg) produced a small amount of soluble activity (NSILA-S) with most of the activity remaining in the precipitate (NSILA-P). It was thought therefore that this represented two distinct molecular species of molecular

weights 6,000 and 90,000 respectively. But it now seems likely that NSILA-P is an artefact generated by the acid/ethanol procedure¹, since with acid extraction alone 90% of the activity is recoverable in the soluble fraction².

Using the insulin-like effects of the material on adipose tissue as a guide, further purification was achieved by molecular sieve chromatography, preparative gel electrophoresis and ion exchange chromatography; finally the activity was isolated in two structurally similar peptides². Since the plasma used as starting material for the isolation of NSILA was pooled from several thousand individuals it is not clear whether these two peptides are the products of two genetic loci in an individual or are allelic variants in the population. Preliminary sequences of the N-terminal region of NSILA-I and NSILA-II reveal that the proteins are very similar to each other and that 50% of the first 30 residues of NSILA-I are identical to the 30 residues of the insulin B chain. This has led Rinderknecht and Humbel to propose that proinsulin may have evolved through gene duplication of an ancestral gene coding for a molecule very similar to NSILA³. It will be interesting to see if the remaining 20 residues of NSILA bear any resemblance to the C peptide of proinsulin which connects the N terminal B chain to the insulin A chain.

Role for NSILA

Many cells examined seemed to have membrane receptors for both insulin and NSILA^{4,5}. The sites are distinct but not surprisingly, in view of the homology of NSILA and insulin, high doses of one hormone will interact with the receptor for the other. This explains why high concentrations of insulin may mimic the effects of physiological levels of NSILA and *vice versa*^{6,7}. The physiological role of insulin is relatively well-understood, what then is the role of NSILA? It is obviously not active *in vivo* as an insulin analogue since diabetic animals have normal plasma levels of NSILA¹. It turns out that NSILA is probably

the major mediator of the effects of the classic trophic hormone, growth hormone.

Growth hormone and somatomedin

The role of growth hormone was determined historically by the observation that hypophysectomised animals fail to grow normally and that this defect can be largely repaired by injection of growth hormone (GH). But attempts to demonstrate the action of GH on skeletal tissue *in vitro* failed until it was realised that GH elicited the appearance of a second hormone that was responsible for many of its attributed physiological effects. This second hormone was originally termed sulphation factor since it was active in promoting sulphate uptake into cartilage. It is now clear however, that this is only one of its activities and amongst other activities it also possesses non-suppressible insulin-like activity. The factor was renamed somatomedin to imply that it mediated the effects of GH (somatotrophin)⁸.

Attempts to purify somatomedin from plasma proceeded on similar lines to those for NSILA, and the purification of a number of peptides with somatomedin (SM) activity has been reported. The biological assay used to guide purification was the incorporation of radioactive sulphate into cartilage, probably a very indirect assay for protein synthesis in the chondrocyte. Indeed, somatomedins have been shown to stimulate RNA and protein synthesis as well as other components of the pleiotypic response in skeletal tissue⁹. Two sources of cartilage are used to follow the purification of somatomedin activity, rat costal cartilage⁹ and chick pelvic leaflets¹⁰. Using the chick assay as a guide the isolation of two somatomedins has been described¹¹. Somatomedin A (SMA) is reported to be a neutral peptide active in the chick assay and somatomedin B (SMB) is an acidic peptide with no activity in the chick cartilage assay but is a growth factor for cultured cells¹². Using the rather more tedious and expensive rat cartilage assay another group of

workers have isolated a basic protein which they term somatomedin C (SMC)⁹. There is now an overwhelming body of evidence suggesting that SMC, SMA and NSILA purified by different groups are either very closely related, or most probably variants of the same molecule, whose active form in the plasma produces the effects of GH.

The probable relationship of SMA and NSILA is suggested by their similar purification schedules, their closely similar physicochemical properties and the fact that at no stage of their purification could insulin-like activity be dissociated from somatomedin activity¹³. Furthermore, these proteins bind to receptors with similar affinity and are displaced by high doses of insulin, and both activities are growth hormone dependent in that levels are low in pituitary dwarfs and high in acromegalics. Initially there was some doubt about the relationship of SMA to SMC and NSILA, as SMC and NSILA were only weakly active in the chick cartilage assay used to detect SMA¹⁴. However, the purified SMA peptide was itself hardly active in this assay although it was active in the rat cartilage system and so possessed SMC activity¹⁵. This puzzle was resolved when it was demonstrated that purified NSILA required the presence of another unidentified serum factor (not under GH control) in order to show sulphation factor activity in the chick assay¹⁶, although stimulation by NSILA of the pleiotypic response in chick cartilage was independent of this serum factor. Furthermore, SMA and SMC compete for the same receptor¹³. Definitive proof that SMA, SMC and NSILA are related must await comparative amino acid sequence data but the need for large amounts of pure material may mean that this proof may take some time.

Trophic action of NSILA

The trophic action of NSILA is not confined to chondrocytes; the factor is very active on cultured animal cells in promoting the parameters of the pleiotypic response and DNA synthesis^{2,17}. Insulin at pharmacological levels has often been used as a growth factor for cultured cells, and the reason for its effect can now be seen to be due to its cross reaction with NSILA receptors on the cell surface. In fact, physiological doses of NSILA have marked trophic effects in cell culture, so NSILA is probably an important member of the elusive serum factors and is quite possibly the one of major physiological relevance.

With so much NSILA in the plasma why aren't animals permanently hypoglycaemic? The answer seems to be that plasma contains a specific binding protein for NSILA which limits its

Table 1 Some of the properties of NSILA and somatomedin

*Full activity in this assay probably requires the presence of another serum factor.

diffusion across capillaries into the extravascular space¹⁸. This helps to explain why the concentration of NSILA in lymph is half that in plasma¹⁹ whereas insulin (which has no binding protein) can equilibrate between these two compartments. The most intriguing feature of this binding protein is that its concentration in the plasma is regulated by GH^{20,21} and the binding of NSILA to its binding protein prolongs NSILA's half-life in plasma from a few minutes to several hours. The release of NSILA from its binding protein is thus a major factor in governing the availability of this growth promoting hormone to the tissues of the body. This also explains why searches in various organs for high concentrations of NSILA were unsuccessful; NSILA is concentrated in one of the largest 'organs' of the body—the plasma.

collaborators who find some homologies in peptide sequences between the cholera toxin and thyroid-stimulating hormone (TSH). Mullin *et al.* *Proc. natn. Acad. Sci. U.S.A.* **73**, 842, 1679; 1976; Ledley *et al.* *Biochem. biophys. Res. Commun.* **69**, 852; 1976; Meldolesi *et al.* *Proc. natn. Acad. Sci. U.S.A.* **73**, 4060; 1976). For this reason alone, current research on bacterial toxin structure and action has wide implications.

Several recent papers provide detailed information on the structure of tetanus and diphtheria toxins. These two toxins superficially have very similar structures and in the native state consist of single polypeptide chains which are easily 'nicked' by proteases into two polypeptides held together by disulphide bonds. Both polypeptide 'subunits' are essential for the activity of either toxin on intact cells. One of the fragments of 'nicked' diphtheria toxin (A subunit), however, is active in inhibiting protein synthesis in cell-free extracts by inactivating elongation factor 2 (translocase) in precisely the same way as intact toxin exerts its killing effect on unbroken cells. The second polypeptide subunit of nicked diphtheria or tetanus toxin then is reasonably assumed to be required to attach the toxin to the surface membrane of whole cells. Until recently this point was hard to establish for diphtheria toxin, since the B subunit is insoluble under normal conditions after disulphide bond cleavage of nicked toxin and may be kept in soluble form only in urea or other protein denaturants. Two groups have now devised methods for the isolation of stable B fragments. Helting and Zwisler (*Behring Inst. Mitt.* No. 59, 92–101, 1976) treated diphtheria toxin with formaldehyde under mild conditions before trypsinisation and reduction of disulphide bonds. The B fragment was immunogenic in rabbits or guinea pigs and the specific antibodies elicited by immunisation blocked the lethal action of diphtheria toxin in animals or whole cells, presumably by interfering with the interaction of the appropriate peptide sequence of the toxin with specific surface membrane receptors. In contrast, these antibodies failed completely to affect the enzymatic activity of isolated fragment A in inhibiting *in vitro* protein synthesis. More direct evidence for fragment B interactions with cells was obtained by Everse *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **74**, 472; 1976). The chains were stabilised either by using low concentrations of sodium dodecyl sulphate or by sulphonation. Solutions containing B fragment protected HeLa cells from the effect of intact diphtheria toxin, while A fragment was completely inactive. Although rather large

amounts of B fragment were required for protection against the toxin the effect does seem to be specific and strengthens the idea that the B fragment of the toxin molecule probably exerts the initial interaction with cell membrane receptors. Everse *et al.* also showed that 'unnicked' toxin was inactive when tested against HeLa cells under conditions where the 'nicked' toxin was highly cytotoxic. Probably, therefore, interaction of the toxin with cell surface receptors takes place most efficiently after 'nicking', a point that is interesting in the context of reports that some tumour cells are more sensitive to the action of diphtheria toxin than normal cells (Iglewski & Rittenberg *Proc. natn. Acad. Sci. U.S.A.*, **71**, 2707; 1974; Pappenheimer & Randall *Proc. natn. Acad. Sci. U.S.A.* **72**, 3149; 1975) and the induction of proteolytic enzymes in some transformed cell lines (see for example Chen & Buchanan *Proc. natn. Acad. Sci. U.S.A.* **72**, 1132; 1975).

The subunit of 'nicked' tetanus toxin analogous to fragment B of diphtheria toxin has also been identified recently (Helting & Zwisler *J. biol. Chem.* **252**, 187; 1977; Helting *et al. J. biol. Chem.* **252**, 194; 1977). The larger of the two polypeptides (heavy chain) derived after mild trypsinisation retained all of the receptor binding activity of the native toxin and a specific antiserum directed against a part of the heavy chain completely prevented activity of whole toxin. These new techniques, therefore, make available stable fragments of both diphtheria and tetanus toxin that are efficient in eliciting antibodies which interfere with the interactions with brain receptors and neutralise toxic action. Such vaccines may have advantages over the standard preparations against inactivated toxoids. Reactions of delayed hypersensitivity are known in immunisation, particularly of older children, for example (see Helting & Zwisler *op. cit.* 1976) and the use of peptide fragments lacking the antigenic determinants producing these undesirable responses would be a distinct advance. □

Toxin subunits

from a Correspondent

DURING the past couple of years knowledge of the mechanism of action of bacterial toxins, particularly cholera, tetanus and diphtheria toxins, and studies of hormone action have pointed out several areas of similarity in these diverse biological systems. Apparently, similar surface membrane receptors may be part of the systems responsible for uptake of some toxins and hormones, an obligatory step in the biological action of these substances on cells. Perhaps the most striking result comes from L. D. Kohn and his

Microtubes

from Peter J. Smith

EVERY now and then someone decides to investigate a terrestrial phenomenon which has been known for many decades, if not a hundred years or more, but which has never before been studied in any detail. Quite why certain phenomena should be ignored for so long is far from clear. Some have probably been considered trivial—of interest in themselves, perhaps,

but with no potential for influencing other branches of the Earth sciences and thus of no significance to the geological mainstream. But not all examples of scientific neglect can be explained away so easily. Consider, for instance, the microscopic tubes, or microtubes, in igneous rocks. There must be a reason for their presence; and an obvious case can be made for saying that they should be able to provide valuable information on the history of their hosts. Yet unlike primary and secondary inclusions in rocks, about which there is now a vast literature, they have been almost completely overlooked.

Richter and Simmons (*Earth planet. Sci. Lett.* **34**, 1; 1977), who have begun a detailed study of microtubes, define them as cavities of circular or elliptical cross section and having diameters generally less than $5\text{ }\mu\text{m}$ and lengths greater than $10\text{ }\mu\text{m}$. They may be hollow or partly or completely filled with a solid phase, but they are distinct from the better-known euhedral needle-like inclusions of minerals such as rutile and apatite. They are also distinct from microcracks, which have one dimension (generally less than a few micrometres) much smaller than the other two (greater than several tens of micrometres). They do not have faceted walls and so can be neither negative crystal forms of the host grain nor the result of acicular inclusions. Yet they are evidently single crystal phenomena, for they never cross grain boundaries.

The first known reference to microtubes was by Sorby (*Q. Jl Geol. Soc.* **14**, 453; 1858) who recognised several isolated examples in vein quartz but made little comment about them. Then Rosenbusch (*Mikroskopische Physiographie der Massigen Gesteine*, Stuttgart, 1907) found very fine cylindrical canals in samples of deformed granite, concluding that they were formed by stresses incurred during mountain building; and Honess (*The Nature, Origin and Interpretation of Etch Figures on Crystals*, New York, 1927) later discovered tubular etch pits in natural quartz. More recently only a handful of workers have mentioned the presence of microtubes and even fewer have commented on them more than briefly, thereby giving the impression that such features are rare. Yet they are very far from rare. They may have been overlooked by many petrographers; but Richter and Simmons have observed them in granite, quartz monzonite, syenite, granodiorite, anorthosite, diabase, gabbro and even lunar basalt, the minerals involved being quartz, K-feldspar,

plagioclase, muscovite, biotite, pyroxene and olivine.

So microtubes are evidently more common than previously supposed. But how do they form? Richter and Simmons conclude from petrographic and scanning electron microscope studies that there is no single process of formation but at least three. It is clear from their groupings, associations and spatial relationships that many microtubes arise from the partial annealing of microcracks. Others, however, appear to have resulted from the etching of crystal defects such as dislocations by naturally occurring fluids, whilst still others are evidently primary features produced by the inclusion of fluid material during crystal growth.

There may be other, as yet undiscovered, ways in which microtubes

form. But such diversity is an advantage, for it suggests even more strongly that the study of microtubes may throw light on the various physical and chemical conditions to which many igneous rocks may be subject both during and subsequent to their formation. Microtubes resulting from annealing might give information on a rock's deformation history, etch tubes could possibly provide evidence of the types of fluid that have circulated through a rock; and primary tubes should provide clues to the conditions obtaining during crystal growth. For the time being Richter and Simmons pursue these possibilities no further; but it is clear from the progress they have made so far that it may have been a mistake to have given microtubes so little attention in the past.

Sex ratios in social insects

from John Krebs

IN a paper published just over a year ago, R. L. Trivers and H. Hare (*Science* **191**, 249; 1976; see also Krebs & May *Nature* **260**, 9; 1976) reported results which in one fell swoop appeared to verify Fisher's theory of the sex ratio, Hamilton's kinship theory of altruism in social hymenoptera, and Trivers's own ideas on manipulation of parents by offspring; a virtuoso display indeed! This seminal and apparently incontrovertible piece of work has now come under vigorous attack from R. D. Alexander and P. W. Sherman (*Science* **196**, 494; 1977).

To recap on the previous story, Trivers and Hare accounted for the apparent altruism of sterile female workers of social hymenoptera such as bees and ants in the following way. As a result of the sex determination system, in which haploid males develop from unfertilised eggs, the diploid females share $3/4$ of their genes by direct descent with their full sisters, and $1/4$ with full brothers. The diploid mothers share half their genes with sons and daughters alike. As W. D. Hamilton first showed, this state of affairs means that a female who has the "choice" between producing her own daughters or rearing reproductive younger sisters makes a genetic profit by doing the latter. However, in order to explain fully the evolution of sterile worker castes in terms of Hamilton's kin selection theory, one has to consider why the workers also rear brothers (with whom they share only $1/4$ of their genes). Trivers and Hare, following up a suggestion of Hamilton, pointed out that workers should be

more prone to rear reproductive sisters than drones. More precisely, they should invest three times as much effort in rearing new queens. If drones are only a third as common as queens they will have on average three times the mating success, which as far as a worker is concerned, exactly compensates for the threefold difference in relatedness. In any typical diploid outbreeding species, the mother's optimal ratio of investment in daughters and sons is 50:50. (This is the only stable equilibrium since the rarer sex is always at an advantage.) Trivers's and Hare's striking finding was that the ratio of investment in 21 species of monogynous (one active queen per colony) ants was close to 3:1 in favour of females, just as predicted by the simplest genetic model based on the assumption of worker success in manipulating the sex ratio to their advantage. As a 'control', Trivers and Hare showed that the investment ratio was much closer to 1:1 in slave-making ants and non-social hymenoptera where the queen presumably achieves her optimum. Far from the picture of selfless worker altruism, these remarkable results suggest that the queen is, in effect, farmed by the workers as a reproduction machine.

Alexander and Sherman question not only the factual basis and statistical treatment of Trivers's and Hare's evidence but also point to an alternative interpretation. The critique is detailed and complex and I can only highlight a few points. Three main

challenges to the factual evidence emerge: multiple matings are commoner than Trivers and Hare assume; workers often lay eggs which develop into drones; and the investment ratio in slave-making ants, termites, and non-social bees and wasps seems to be slightly biased towards females.

The calculations of degree of relatedness on which Trivers's and Hare's predictions are based depend critically on their assumption that the workers and the reproductive females these rear are full sisters. If the queen mated with three males and mixed the sperm at random, the whole argument for a bias on the part of workers would collapse. Alexander and Sherman point out that multiple matings are quite common in social hymenoptera. But the problem is that single matings are virtually impossible to prove even if they are common. One might also add that the mating habits of present-day queens are probably less critical to Trivers's and Hare's argument than those of queens during the early evolution of eusociality: studies of mating in the semisocial hymenoptera suggest that monogamy may have been quite common at this intermediate evolutionary stage.

The kinship theory of social hymenoptera does in fact predict that workers should attempt to lay eggs, since by so doing they substitute sons (degree of relatedness $1/2$) for brothers (to whom they are related by only $1/4$). This point was discussed at length by Trivers and Hare, who consider egg laying to be an alternative strategy to manipulating the investment ratio by workers. The only point in question is whether the monogynous ants selected for analysis by Trivers and Hare are species in which the sex ratio is influenced by laying workers, a point on which there seems to be no concrete evidence.

Alexander's and Sherman's doubts concerning the claims of Trivers and Hare that the ratio of investment in slave-making ants, termites, and non-social hymenoptera is close to 1:1 stem from the fact that the original data are incredibly variable, some nests showing a strong female bias and others a trend towards males. Alexander and Sherman conclude that the termites show a slight female bias (kinship theory predicts no bias) and that some of the data for unsocial bees and wasps used by Trivers and Hare may be subject to the sampling bias. Nevertheless they admit that the basic trend—a stronger female bias in investment ratio in monogynous ants than in non-social hymenoptera—is still valid.

Much more important than these hair-splitting criticisms, is Alexander's and Sherman's suggestion that a plausible alternative hypothesis could

account for the results obtained by Trivers and Hare. Interestingly, this alternative idea was also developed by W. D. Hamilton, who pointed out that Fisher's theory of equilibrium sex ratios does not hold when there is inbreeding and siblings compete with each other for matings (as males usually compete for females rather than *vice versa*, the argument can be taken to refer to competition between brothers). Suppose, for example, that a female's daughters are all fertilised by their brothers. The mother's best strategy is to produce just enough males to ensure that all daughters are fertilised, putting most of her resources into female offspring. Fisher's 1:1 equilibrium no longer holds, because the expected reproductive success of sons does not depend on what goes on in the rest of the population. Whenever this sort of competition between brothers occurs the optimal sex ratio will be biased towards females, the exact bias depending on the degree of inbreeding.

If, as Alexander and Sherman suggest, inbreeding and sibling competition for mates is common in social hymenoptera, the biased investment ratio might be optimal for the queen and not, as Trivers and Hare suggest, for the workers, who would like a still greater bias in favour of females. The two hypotheses, both apparently consistent with the data, are not necessarily mutually exclusive. The mean investment ratio for the monogynous ants analysed by Trivers and Hare was about 3.5, slightly in excess of the predicted 3.0. This could conceivably be an effect of both mating competition and worker manipulation, although one cannot check this as Alexander and Sherman are unable to predict an optimal investment ratio for the queen without more information on the extent of mating competition.

Trivers's and Hare's hypothesis, on the other hand, not only predicts with reasonable success (given the difficulty of measuring 'investment') the observed bias in monogynous ants, but also predicts the difference in investment ratio between monogynous ants on the one hand, and the slave-making ants, non-social bees and termites on the other. In order to account for this difference, Alexander and Sherman have to invoke the (plausible) argument that inbreeding is less common in the second group than in the first. (They also point out that among the non-social hymenoptera, a slight female bias in the sex ratio is more often observed in those species which do have inbreeding).

To sum up, although the evidence is not as clear cut as it first appeared, Trivers's and Hare's hypothesis still provides the more parsimonious pre-

dictive explanation of the data, and what is more, it also predicts other observations, for instance laying by workers, and the absence of sterile males in the hymenoptera but not in the termites. Nevertheless the sex ratio is almost certainly modified to some extent by inbreeding. □

Low temperature electron microscopy

from Patrick Echlin

The 1st International Meeting on Low Temperature Biological Microscopy was held in Cambridge 4-7 April, 1977 under the auspices of the Royal Microscopical Society. Edited versions of all the papers will appear later this year in the *Journal of Microscopy*.

ALTHOUGH low temperature techniques are now assuming a greater significance in biological investigations, many biologists are unhappily unaware of the complex physicochemical properties of ice and the nature of the freezing process in cells and tissues. This interdisciplinary meeting sought to redress this situation by bringing together ice physicists, physical chemists, cryobiologists, engineers and microscopists to see whether these techniques are indeed fulfilling the promise of perfect preservation of ultrastructure and functional physiology. All the participants overtly or tacitly accepted the dictum that 'cold is good' but there was extensive discussion as to what constitutes 'good' in relation to ultrastructure, analysis and vitality. J. Farrant (Clinical Research Centre, Harrow) showed that with a few exceptions good ultrastructure, retention of soluble constituents and preservation of vitality were probably always likely to be mutually exclusive. This, the cryobiologist's trinity, could only be achieved by vitrification, a process rarely achieved in biological tissues.

Various techniques which would help overcome the problems associated with ice crystal damage were discussed. H. Sitte (University of Homburg-Saar), H. Muller (Technical High School, Zurich), W. Bald (University of Oxford) and L. Seveus (Stockholm) described new fast-freezing techniques, all of which could theoretically give sufficiently fast cooling velocities in small pieces of biological material to bring about a shift from heterogeneous nucleation to homogenous nucleation with the consequent formation of very small ice crystals. Alter-

Patrick Echlin is Deputy Director of Research in the Botany School in the University of Cambridge.

native approaches were offered by T. Nei (University of Sapporo, Japan), H. Skaer (University of Cambridge) and A. Walter (Clinical Research Centre, Harrow) who advocated the use of penetrating and non-penetrating cryoprotectants. Nei showed images of remarkable preservation in red blood cells frozen and thawed in the presence of 20% glycerol, and Skaer gave details of some high molecular weight polymers which although they do not enter cells, limit the size of intracellular ice crystals to nanometre dimensions even in pieces of tissue 1 mm in diameter. Such polymers have important implications in the preparation of tissues for freeze fracture and X-ray microanalytical studies which are best carried out on chemically unperturbed tissues.

There was extensive discussion on the process of sectioning and freeze fracturing and the nature and extent of the artefacts associated with these techniques. A. Saubermann (Harvard Medical School) demonstrated that the process of cutting frozen material is a mixture of sectioning and multiple fracturing depending on temperature, cutting speed and knife angle, and U. Sleytr (Vienna) and T. Robards (University of York) showed that plastic deformation can occur at temperatures well below the glass transformation point of ice. Sufficient energy is released during cleavage to deform biological material and great care must be taken when interpreting freeze fracture images. The same point was taken up by D. Branton (Harvard University) and S. Bullivant (University of Auckland) who showed that some of the artefacts associated with membrane structure are produced either during specimen pretreatment and freezing or simply by the collapse of the lipid layers after membrane cleavage.

Low temperature techniques are clearly no longer the preserve of the morphologists and a number of papers were given showing how both frozen-hydrated and frozen-dried tissues and sections could be used for the analysis of diffusible ions and electrolytes. K. Zierold (Max Planck Institute, Dortmund) and M. Sjostrom (University of Umea, Sweden) gave details of low temperature X-ray analytical studies on mammalian muscle. T. Barnard (Wenner-Gren Institute, Stockholm) related the diffusion of electrolytes in frozen sections of adipose tissue to changes in the electron density of the sections. One of the main problems of low temperature microscopy is to ensure that the biological material stays cold enough during preparation and examination. P. Echlin (University of Cambridge) considered these problems in relation to cryofractured frozen bulk samples and sections examined at

low temperatures in the scanning electron microscope and suggested a number of criteria which could be used to judge the hydration state of material in the microscope. Such problems are less exacting for the smaller samples examined by K. Taylor (MRC Laboratory of Molecular Biology, Cambridge) in the transmission microscope who used the disappearance of the ice diffraction pattern as an indicator of specimen hydration in catalase crystals and bacterial cell walls. There were close similarities between the negative stain images of catalase and the hydrated crystals, and it looked as if the ice was acting rather like a negative stain. The earlier hopes that low temperatures might dramatically diminish radiation damage in high resolution images were dashed when R. Glaeser (University of California, Berkeley) showed that depending on the specimen, the damage is only lessened by a factor of two when operating at liquid nitrogen temperatures and a factor of five when operating only a few degrees above absolute zero.

There was considerable discussion on the interpretation of morphological data obtained from frozen sections and fractures. T. Gulik-Krzywicki (CNRS Gif-sur-Yvette) showed that it is possible to correlate low temperature X-ray diffraction patterns with images obtained by freeze fracture electron microscopy, and H. Chanzy (CNRS Grenoble) described a technique for low temperature electron diffraction. Whereas these specialised techniques and the use of image processing can help with the interpretation of the inert freeze fracture images, such methods are of little use for unstained frozen sections which give images containing few of the subcellular features recognisable from conventional microscopy. Cryohistologists are going to have to re-educate themselves to recognise images in material produced and examined at low temperatures. □

Head-on proton collisions

from Peter Landshoff

MOST of the information on the structure of protons has been obtained by bombarding them with very high energy electrons, and these are the experiments that have provided strong, though indirect, evidence that protons contain quarks. The quarks apparently

Peter Landshoff is Reader in Mathematical Physics at Cambridge University.

A hundred years ago

THE Superintendent's Report on the Botanic Garden and Public Plantations for 1875-76 has recently been officially published in Jamaica. It deals almost entirely with plants of economic value, foremost of which is the coffee, the ordinary kind (*Coffea arabica*), apparently giving way to its formidable rival *Coffea liberica*, which was introduced to Jamaica in 1874, and is now thriving, especially in some districts. In one situation, at a height of about 1,000 feet above the sea, a plant that had only been planted out a little over a year has already fruited. This seems to indicate that in the course of a few years the new coffee may be widely cultivated in Jamaica from plants raised from seeds ripened in the island.

From *Nature* 16, 24 May, 73; 1877.

have very small diameters, or are maybe even pointlike, although the proton as a whole has a more diffuse structure in which the quarks are embedded. The nature of the remaining constituents is not yet clear. Certainly they include quark-antiquark pairs, some of which may be bound tightly together to form mesons. Very possibly they include also the 'gluons' that bind quarks and antiquarks together in the quantum field theories that mathematical physicists are constructing in attempts to unify the various fundamental forces of nature.

The evidence that there are quarks inside the proton is indirect, because no free quarks have yet been seen. Indeed, many physicists believe that it may not be possible for quarks to be knocked out of their parent protons. (There have been various attempts to construct such theories of 'quark confinement'.) For this reason, it is desirable to verify the quark structure in other types of experiment. Beams of high-energy muons and neutrinos have also been used to probe the proton, and the information that they give, while again indirect, seems to confirm and complement that which comes from electron scattering. A quark structure in the proton seems rather sure.

Electrons, muons and neutrinos are particularly useful as probes because their own structure is especially simple and well understood. However, additional information can be obtained by making pairs of protons collide at very high energy.

The diameter of a proton is about 10^{-12} m—much greater than that of a quark, but infinitesimal compared with the width of a laboratory proton beam. So when two high energy beams are fired at each other, as in the Intersecting Storage Rings of the European laboratory at CERN, most of the protons do not collide. Those that do nearly always are in glancing collision. The dynamics of such collisions, where only the outer parts of the two protons interact, is complicated. It does not involve the quark structure in a very direct way, and the particles produced in the interaction (mostly pions) are swept along more or less in the initial directions of the two colliding beams.

Very rarely, two protons collide head-on and in this case their quark structure may be expected to be involved rather directly. Also, the head-on collisions are quite likely to produce particles that emerge with a fast sideways motion relative to the initial beams. Although these 'large-transverse-momentum' events are comparatively very rare, they can readily be identified, and their study has been an important part of the CERN Intersecting Storage Rings research programme during the past four or five years. Some important information has come also from experiments at Fermilab in the United States.

High-energy proton-proton collisions produce a large number of additional particles, making the analysis of the interesting events complicated. So far the analysis cannot be complete because of the limitations of the available particle detectors. However, several of the CERN experiments have recently observed an interesting "jet structure" in the large-transverse-momentum events: the sideways-moving particles emerge together in more or less the same direction, so as to form a jet of particles. This jet structure has been seen most clearly in three experiments using the CERN Split Field Magnet facility. These experiments were performed by a group from CERN, by a CERN-College de France-Heidelberg-Karlsruhe collaboration, and by a British-Scandinavian-French collaboration. More recently, a collaboration from Caltech, UCLA, Fermilab, Chicago and Indiana has reported results from a jet study at Fermilab. The total momentum of the two protons that collide is zero, so there are two jets, one emerging to each side of the initial beam direction (see Fig. 1). In addition to the two jets, several particles are produced that have small transverse momentum, as in the ordinary, glancing collisions.

Pairs of jets are known also to be a feature of collisions of high-energy electrons with positrons. In these col-

Transcriptional control of fertility

from J. R. Saunders

A RECENT paper from Neil Willetts (*J. molec. Biol.* **112**, 141; 1977) provides the first biochemical evidence that the fertility of bacterial plasmids is regulated at the level of transcription. Most of the genes specifying the ability to conjugate in *Escherichia coli* comprise a single 'transfer operon' which is present on the F factor and F-like plasmids. This operon consists of genes necessary for the production of sex pili, for surface exclusion and for the metabolism of DNA during transfer. It is transcribed in the order *traA*, *traL*, *traE*, *traK*, *traC*, *traF*, *traH*, *traG*, *traS*, *traD* (Helmuth & Achtman *Nature* **257**, 652; 1975). A further gene *traJ*, has a positive controlling function over the entire operon but lies outside it. In turn the expression of *traJ* is itself subject to negative control imposed by two further plasmid genes *finO* and *finP* acting in concert. F-like plasmids isolated from the wild generally transfer at a relatively low frequency due to this control. F itself is atypical in that it is a naturally occurring *finO*⁻ mutant and consequently transfers itself at a high rate. However F will recognise the *finO* product specified by other F-like plasmids and if present in the same cell such plasmids inhibit F fertility producing the *Fin*⁺ (*fi*⁺) phenotype.

Genetic tests have established that the gene products of the transfer operon are absent during *FinOP* fertility inhibition. Hitherto it was unclear whether the *traJ* product is necessary for transcription or translation of the operon. Willetts has distinguished between these possibilities by first constructing bacteriophage λ transducing phages carrying either *traJ* or the *traL*, *traE*, *traK* region. He then used DNA from these phages as probes for the synthesis of specific messenger RNA during *FinOP* transfer inhibition. His hybridisation experiments indicate that whilst mRNA homologous with this '*tra*' DNA is present in donor strains carrying F alone it cannot be found during transfer inhibition of F by the F-like R plasmid R100. This suggests that the transcription of *traJ* is repressed under the latter conditions. In the absence of the *traJ* product, transcription of the transfer operon itself is either not initiated or possibly terminated prematurely shortly after initiation. It should prove possible now to extend these studies on the expression of sex factors by utilising λ *tra* phages carrying further transfer regions of F and other plasmids.

J. R. Saunders is a lecturer in the Department of Microbiology in the University of Liverpool.

lisions, the electron and the positron annihilate each other. There is convincing evidence that the energy that they leave behind subsequently materialises as a quark and an anti-quark, which apparently do not escape as free particles. Exactly what happens is not understood, but first they "dress" themselves somehow by interacting with each other, so that they then emerge as two jets of ordinary particles. There are also indications that similar jets result from the collisions of high-energy electrons, muons or neutrinos on protons.

Because there is good evidence that

Fig. 1 The two jets produced in large-transverse-momentum collisions together with particles that have small transverse momentum relative to the incoming beams.

these jets originate from quarks, a natural guess is that the same may be true of the jets produced in the large-transverse-momentum proton-proton collisions. In the simplest model for this reaction, a quark from one of the protons scatters a quark from the other through a wide angle. The two quarks then somehow dress themselves, and result in the two jets. The remaining constituents of the two protons are responsible for the production of the longitudinally-moving particles.

There are other models that differ in detail. The experimental and theoretical question of whether the jets seen in proton-proton collisions do have the same character as those in electron-positron annihilation has yet to be answered. But it is already apparent that the large-transverse-momentum proton-proton reactions have fairly simple features which, in a way whose details are still to be determined, do reflect the quark structure of the proton. When the dynamics of these reactions are better understood, they will provide a unique way of investigating how quarks scatter on each other at high energies.

Magma mixing: a mechanism for triggering acid explosive eruptions

Stephen R. J. Sparks & Haraldur Sigurdsson

Graduate School of Oceanography, University of Rhode Island, Kingston, R.I. 02881

Lionel Wilson

Lunar and Planetary Unit, Environmental Science Dept., University of Lancaster, Lancaster, UK

Injection of basic magma into acid magma causes superheating of the acid magma and vigorous convection. Vesiculation induced by convection and increased magma pressure fractures the volcanic edifice triggering an explosive acid eruption. The 1875 plinian eruption of Askja, Iceland is an example of an explosive eruption triggered by magma mixing.

THERE are many possible mechanisms of triggering explosive volcanic eruptions of acid magma. Most of these involve factors which ultimately lead to supersaturation of the melt with respect to volatiles¹. We have, however, been impressed by a number of examples of plinian pumice fall deposits where there is evidence that basic magma was intruded into acid magma and the two magmas were physically mixed by vigorous convection shortly before eruption. We will now describe this evidence and demonstrate theoretically that a number of effects of mixing are highly conducive to triggering an eruption. We propose that magma mixing is a common mechanism of triggering explosive eruptions of acid magma, although we emphasise that not all magmas that mix inevitably erupt, nor are all explosive eruptions caused by mixing.

Geological evidence

Tephra containing an intimate mixture of two or more contrasted compositions of magma is a common feature of acidic pyroclastic deposits and in our view the few examples described in the literature do not adequately reflect the abundance of mixed tephra occurrences²⁻⁶. In the cases observed by us the more basic component occurs either as bands and streaks or as irregular, rounded clots and inclusions in the acid pumice. The basic component is usually a volumetrically minor component, but shows evidence of its molten condition at the time of eruption by the occurrences of vesicles, flowage structures and its glassy condition. We now describe detailed case histories of explosive ejecta which shows these features from Askja, Iceland and Santorini, Greece.

Fig. 1 shows the stratigraphy and lithological characteristics of the mixed ejecta of the 1875 explosive eruption in Askja, Iceland. The layers formed over a period of 8.5 hours on the night of the 28-29 March 1875 (ref. 7). The plinian deposit (layer d) formed in six of those hours and represents 80% of the ejecta by volume. All the tephra layers show evidence of mixing and simultaneous eruption of basalt and rhyolite magma.

We have analysed the two end-member glasses which are found intimately associated in the 1875 ejecta (Table 1; analyses a and b). The basaltic component is a dark brown glass, poor in

crystal, and is similar in composition to the tholeiites which characterise the Northeastern Rift Zone of Iceland⁸. The basaltic glass occurs as irregular inclusions and streaks in rhyolitic obsidian and pumice and occasionally in bombs. More often it is found in separated, rounded, mixed dark scoria fragments. During most of the eruption the scoria clasts were finer than 1.0 cm and hence are progressively enriched in the tephra away from the source where most of the tephra less than 1 cm was deposited. Layer c (Fig. 1) grades laterally into a densely welded air fall tuff where both the

Fig. 1 Schematic section of the 1875 Askja tephra showing the principal lithological characteristics of the five layers. The thicknesses are the maximum observed for each layer on the north-eastern and eastern rims of Oskjuvatn. B refers to base surge horizons.

rhyolitic pumice and basic clasts have been deformed into *flamme*, demonstrating the molten condition of both magmas. During the closing stages of eruption the size of mixed ejecta markedly increased. Large spatter bombs and mixed bombs up to 5 m diameter containing both magmas were ejected.

The rhyolitic component contains less than 1% plagioclase and clinopyroxene crystals and is relatively low in total alkalis and high in CaO and MgO (Table 1) compared to other Icelandic rhyolites⁹. Some plagioclase phenocrysts are rounded but they contain glass inclusions of rhyolitic composition showing that they formed in equilibrium with the acid liquid. The rounding could be interpreted as resorption due to superheating of the rhyolite. Rounded grey clots (0.1–1.0 cm) are found as inclusions in the rhyolitic pumice in all the layers. These inclusions contain between 40% and 50% of plagioclase and pyroxene microphenocrysts set in a pale brown glass. The detailed petrological and volcanological relationships are complex, but are not pertinent to the present considerations. We merely wish to document the highly heterogeneous nature of the ejecta.

Table 1 Analyses of mixed tephra

	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>
SiO ₂	73.72	50.98	69.61	54.1
Al ₂ O ₃	12.92	13.81	14.14	16.6
TiO ₂	0.83	1.89	0.38	0.8
FeO	3.12	13.31	2.89	8.2
MgO	0.57	6.18	0.36	3.3
CaO	2.14	10.82	2.00	8.0

Na ₂ O	3.59	2.47	4.78	5.0
K ₂ O	2.53	0.30	3.07	1.3
P ₂ O ₅	0.12	0.21	0.07	—
H ₂ O	—	—	3.49	2.4
Total	99.61	100.27	100.87	99.8

a. Rhyolitic glassy *flamme* from welded part of layer *c*, Askja (average of 7 analyses); *b*. Basaltic glass, Askja (average of 5 analyses); *c*. Rhyodacite pumice, Santorini; *d*. Basaltic andesite scoria, Santorini. Analyses *a* and *b* were made on the electron microprobe. Analyses *c* and *d* are X.R.F. whole rock analyses (analyst A. Bond).

On the volcano Santorini several of the major acid plinian pumice fall deposits exposed in the caldera walls are mixed. Bond and Sparks¹⁰ recognised the following sequence of products in the Bronze Age Minoan eruption: plinian pumice fall deposit, base surge deposits, mud-flow deposits and ignimbrite. The bulk of the ejecta is rhyodacite containing 10–12% phenocrysts and there is no marked major element variation throughout the sequence. However, the upper half of the plinian deposit and the lower half of the base surge deposits contain vesicular, grey rounded pumice clasts (0.1–5 cm diameter) of basaltic andesite bulk composition (Table 1: analyses 3 and 4), which contain 25 to 35% phenocrysts set in a pale vesicular glass containing abundant quench crystals. The two types are quite distinct (SiO₂ 69.6 and 54.1%) and occur together in the same pumice clast. The tephra in the ignimbrite and lower part of the plinian deposit is not mixed.

Similar relationships are observed in the thick, prehistoric rhyodacitic pumice deposit (Bu) of the Middle Pumices Series¹¹. This deposit has two fall units, the lower one containing white rhyodacitic pumice only. In the upper fall unit grey, olivine bearing basaltic andesite pumice clasts, similar to the Minoan examples, are found intimately mixed with white rhyodacitic pumice. The proportion of basic tephra increases markedly upwards reaching an estimated 30% at the top of the upper fall unit. There are at least 12 acid pumice fall deposits exposed in the caldera walls of Santorini, which we have examined. Seven of these show field evidence of a mixed nature, with

relations between the two components similar to those described in the Minoan and Bu pumice deposits. The more basic component is not necessarily basaltic or indeed greatly different from the acid component: in one deposit the two components have SiO₂ contents of 61.1 and 65.7% respectively.

In these examples from Santorini and Askja mixing of the magmas can only have occurred shortly before eruption. In all cases the basic clasts are still dominantly glassy even in inclusions of a few millimetres size. Such inclusions could not survive in their acid host for any substantial time without either completely crystallising or dissolving by diffusion. In the case of Santorini, radiocarbon dates¹¹ indicate that periods between explosive acid eruptions are of the order 10⁴ yr. The mixing of the magmas can be shown, however, to have occurred no more than a few years before eruption and we believe that periods of weeks are more realistic for the time interval between mixing and eruption.

The interdiffusion of ions between two miscible silicate glasses can be estimated from:

$$l = \beta \sqrt{(Dt)} \quad (1)$$

where *l* is the length to which a diffusional wave penetrates from one area to another in a time *t*, *D* is the diffusion coefficient, and β is a constant which is conveniently 1.0 for 95% of the final equilibrium concentration¹². In the case of a sphere of basaltic glass, the length *l* may be set equal to the radius; for a radius 0.1 cm and for $D = 10^{-9} \text{ cm}^2 \text{ s}^{-1}$, which is typical of ionic diffusion rates at high temperature in silicate melts¹³, *t* is 3.85 months. In the Minoan deposits and Askja deposit, inclusions of basic material of 0.1 cm show little evidence of substantial chemical exchange with their host. We believe that the magmas were intermingled physically, but were erupted before any substantial chemical interaction took place. On Santorini we have observed the same relationships in several deposits and the eruptions clearly coincide with mixing events.

Model for magma mixing

We propose that magma mixing is a process which is likely to trigger an explosive eruption and that the features we have described in Askja and Santorini fit such a model. An acid magma emplaced in the upper crust is a slow moving and slow cooling body. Changes in physical conditions such as temperature and gas pressure will occur gradually, as crystallisation and conductive heat loss proceed, over periods of 10³–10⁵ yr (ref. 14). Gradients of temperature and physical properties will be small and rates of change slow. Intrusion of basic magma into the base of an acid magma chamber would dramatically alter this situation and produce an unstable, non-equilibrium system.

Studies of intrusive net-vein complexes³ show that the basic magma often forms pillow-like accumulations when intruded into acid magma. The temperature contrast between basaltic magma (1,100–1,300 °C) and acid magma (750–950 °C) is substantial. The break up into pillow-like units and inclusions results in an increased rate of heat transfer. The time *t* for a thermal wave to penetrate an object radius *R* can be estimated from

$$t = R^2/8K \quad (1)$$

where *K* is the thermal diffusivity. For a typical pillow 1 m diameter and with $K = 3 \times 10^{-7} \text{ m}^2 \text{ s}^{-1}$ (ref. 14) the value of *t* is approximately 29 h. A basic magma that breaks up into metre or decimetre sized units equilibrates thermally with its immediate surroundings in periods of hours or days. Thus the acid magma host would be locally substantially superheated with extreme rapidity.

Magma mixing is believed to lead to vigorous convection in the acid magma. The superheated acid magma at the base of the chamber becomes less dense than the cooler magma above.

The condition for a convective cell to form is when the Rayleigh number (Ra) exceeds 660 (ref. 15) where

$$Ra = \alpha (\Delta T) d^3 g \rho / K \nu$$

In this expression α is the coefficient of thermal expansion ($= 5 \times 10^{-5} \text{ deg}^{-1}$), ν the viscosity, d the length scale of the chamber, K is the thermal diffusivity, ρ is the density of the acid magma, g is the acceleration due to gravity, and ΔT is the difference in temperature of the two magmas. Substituting values of viscosity (10^6 P), d for a magma in a mixing situation (10–1000 m) and temperature difference (10–300 °C) into the above equation yields Rayleigh numbers of 4×10^6 to 10^{13} . The values are orders of magnitude greater than the critical value.

In a simple model of a two-dimensional laminar convection cell¹⁶ the approximate expression for the vertical velocity in the cell is

$$V = (0.25(Ra)^{2/3} K) / d$$

Substituting the range of Rayleigh numbers estimated above, the vertical velocities range from 3.5 m d^{-1} to $3,000 \text{ m d}^{-1}$. These calculations suggest that magma mixing would produce vigorous and rapid stirring of the acid magma in periods of only days or weeks. The calculations are invalid if convection is turbulent, in which case stirring of the two magmas would be even more rapid. Shaw¹⁴ predicted from the work of Lighthouse¹⁵ that at values of Ra greater than 10^4 a magma would undergo fully turbulent convection. Our estimates of Ra indicate that fully turbulent convection is possible in a magma mixing event.

The likelihood of an eruption is greatly increased by magma mixing and convection. The acid magma is mobilised and magma at the base of the chamber is transported to the top. Our calculations indicate this takes place so rapidly that the magma is completely out of equilibrium with its surroundings. If the magma is saturated with volatiles at the base it will become highly supersaturated as it rises and gas pressures will rapidly build up. Increase of temperature in the acid magma reduces the solubility of gases such as water, thus providing a second, independent mechanism for supersaturating the magma. The volume increase due to the intrusion of basic magma is likely to increase the fluid pressure of the acid magma on its chamber walls, and fractures may form providing a pathway for the acid magma to the surface.

At the same time as the acid magma is superheated, the basic magma is quenched and some crystallisation may occur, resulting in exsolution and transfer of volatiles from the basic to the acid magma. Heating of the acid magma reduces its viscosity and ascent of the acid magma through fractures under a constant pressure gradient becomes more rapid and convection more intense as viscosity is lowered. Figure 2 illustrates schematically the model we envisage.

Triggering of acid explosive eruptions by magma has been observed in two geological settings. In regions of rifting such as Iceland magma mixing is the consequence of the fortuitous intersection of basaltic dykes with bodies of rhyolitic magma within acid volcanic centres. Basaltic injections may principally occur during regional rifting episodes such as the volcano-tectonic event in the north-eastern volcanic zone of Iceland from 20 December 1975 to the time of writing¹⁷.

A similar rifting episode occurred in this region from 1874–1875 (ref. 17). The 1875 Askja eruption was preceded by earthquakes and minor activity for a few months before the main event. This rifting episode was accompanied by injection of basaltic dykes as evidenced by the basaltic Sveinagja fissure eruption of 18 February 1875 north of Askja. We suggest that one or more basaltic dykes intercepted the Askja magma chamber (Fig. 2), so that basaltic magma was injected into rhyolitic magma no more than a few weeks or months before the plinian eruption of March 1875.

Fig. 2 Schematic model of the mechanism of triggering explosive eruptions by magma mixing. *a*. Basic magma is intruded into the base of acid magma. *b*. Pillows are formed and local superheating of the acid magma induces vigorous convection and vesiculation. *c*. The combination of intrusion of basic melt and vesiculation results in an increase in the fluid pressure of the magma system on the confining walls. Fractures form above the magma and an eruption is triggered.

The convection caused by mixing resulted in entrainment of small pieces of basic magma in the acid magma. These became thoroughly mixed throughout the chamber and so accounted for the simultaneous eruption of rhyolitic tephra with minor amounts of basaltic and mixed tephra from the beginning to the end of the eruption (Fig. 2*b*). At the end of the eruption the level of the magma had fallen to the base of the chamber where the size of basaltic units within the acid magma increases (Fig. 2*c*).

In island arc volcanoes, magma mixing may occur while magma enters from source regions into high level magma chambers. Anderson¹⁸ has provided convincing evidence that some andesite lavas are examples of magmas where both physical and chemical mixing have occurred well before eruption. On Santorini the field evidence is consistent with a small proportion of basic magma being mixed with large volumes of acid magma without substantial chemical interaction shortly before eruption.

In the model (Fig. 2) it is entirely possible that a large part of the basic magma is never erupted. Being considerably denser than their acid host large pieces of basaltic magma will remain at the base. Only inclusions of sufficiently small size will be entrained and mixed throughout the magma. Basic magma may induce convection in acid magma and eruption without being ejected itself. The possibility exists that magma mixing may have a role in eruptions other than those for which there is direct evidence of mixing.

Injection of basic magma into an acid magma chamber results in rapid superheating and induces convection of the acid magma, resulting in entrainment and physical mixing of some of the basic magma. Superheating and decompression of parts of the acid magma due to convection leads to supersaturation of volatile phases and vesiculation. The injection of basic magma and vesiculation of the acid magma markedly increases the pressure exerted by the acid magma on the confining walls. We believe that this pressure increase may often be sufficient to fracture the volcanic edifice and thus trigger an explosive eruption.

The Royal Society supported field work in Iceland. S. R. J. S. acknowledges a NATO post-doctoral fellowship. Parts of the research were funded by NSF grants. We thank G. P. L. Walker and N. D. Watkins for helpful comments. The whole rock analyses of Santorini tephra were carried out by A. Bond. The authors thank the Icelandic Research Council and the

Greek Institution of Mining for permission to carry out research in their countries.

Note added in proof: Another possible consequence of mixing of magmas is water supersaturation due to resorption of calcic plagioclase into the rhyolitic melt, which has been demonstrated experimentally by Yoder¹⁹.

Magnetostratigraphy of the Cretaceous-Tertiary boundary in the San Juan Basin, New Mexico

Robert F. Butler, Everett H. Lindsay & Louis L. Jacobs

Department of Geosciences, University of Arizona, Tucson, Arizona 85721

Noye M. Johnson

Department of Earth Sciences, Dartmouth College, Hanover, New Hampshire 03755

Magnetostratigraphy of a terrestrial sedimentary sequence in the San Juan Basin reveals that the Cretaceous-Tertiary boundary, recognised by the highest stratigraphic occurrence of dinosaurs, is younger than the midpoint of marine magnetic anomaly 29. This boundary is slightly younger than, but very close to, the Cretaceous-Tertiary boundary in the marine sedimentary sequence at Gubbio, Italy, which has recently been proposed as the magnetostratigraphic type section for the Upper Cretaceous and Palaeocene.

FAUNAL succession provides the major basis for recognition of geologic-time units. Boundaries between geologic-time units are placed at points of significant change in the fossil record, such as extinction of major elements of the fauna (here we use 'geologic-time boundary' in the practical sense of boundaries between biostratigraphic units recognised as belonging to different time intervals, but see ref. 1). These boundaries are generally considered to be globally synchronous. Geologic-time units and boundaries are generally defined in marine sequences. These units and boundaries must, then, be correlated with terrestrial sequences on the basis of other criteria. For example, the Cretaceous-Tertiary boundary is defined by extinction of invertebrates (primarily ammonites) in marine sequences but is recognised in terrestrial sequences by the last occurrence of dinosaur fossils. Thus, the global synchronicity of geologic-time boundaries has never been demonstrated. The resolution of this matter has implications for correlation of faunal changes in marine and terrestrial environments, as well as for geochronology itself.

Isotopic dating of horizons within various marine and terrestrial sequences has greatly refined knowledge of age limits and synchronicity of many geologic-time boundaries, but these techniques are not sufficiently precise to resolve the question of global synchronism. To test synchronicity of geologic-time boundaries, a globally synchronous phenomenon must be recorded in both marine and terrestrial sedimentary sequences. Geomagnetic polarity reversals are globally synchronous phenomena² and provide a technique for testing synchronicity of geologic-time boundaries.

Determination of palaeomagnetic polarity stratigraphy in sequences of marine and terrestrial sediments bracketing a particular geologic-time boundary can provide the data necessary to reveal the synchronism or lack of synchronicity of that boundary.

Significant changes occur in both invertebrate and vertebrate faunas at the boundary between the Cretaceous and Tertiary Periods (also Mesozoic and Cainozoic Eras). Through the Deep Sea Drilling Project (DSDP), the earliest foraminiferal zones deposited on oceanic crust of known magnetic anomaly number are providing valuable information on the alignment of invertebrate biostratigraphy with the magnetic anomaly time scale^{3,4}. As a result, considerable progress has been made in referring faunal changes at the Cretaceous-Tertiary boundary in marine sequences to a point in the geomagnetic polarity time scale. These data are complemented by palaeomagnetic polarity determinations on DSDP cores⁵. In addition, Alvarez *et al.*⁶ have proposed a magnetostratigraphic type section for Upper Cretaceous and Palaeocene in Gubbio, Italy. The Cretaceous-Tertiary boundary in this marine sequence occurs near the top of the reversed polarity interval preceding magnetic anomaly number 29.

The San Juan Basin, New Mexico and Colorado, contains a complete Upper Cretaceous into Lower Tertiary sequence of terrestrial sediments. We report here the results of a palaeomagnetic and palaeontologic investigation of the sediments embracing the Cretaceous-Tertiary boundary. These data are an important step toward resolution of the Cretaceous-Tertiary boundary in terrestrial sedimentary sequences, and its comparison with the Italian marine sequence is valuable in evaluating the global synchronism of this important geologic-time boundary.

Stratigraphy and vertebrate palaeontology

The San Juan Basin, located in northwest New Mexico and southwest Colorado, contains one of the most complete Palaeocene terrestrial stratigraphic successions in the world. The Palaeocene sediments are underlain by late Cretaceous and are overlain by early Eocene strata. The terrestrial sedimentary sequence in the San Juan Basin proceeds from shales and interbedded coal layers of the Fruitland Formation, through shales, siltstones and sandstones of the Kirt-

Fig. 1 Trend of the palaeomagnetic section and location of vertebrate fossils. Distribution of geological formations is after Bauer¹². Fossil localities: F, Ojo Alamo local fauna; G and H, *Ectoconus* and *Taeniolabis* zones, respectively, of the Puercan Land Mammal Age.

land Formation, and into conglomeratic sandstone and interbedded shale of the Ojo Alamo Formation. These dinosaur-bearing formations are overlain by varicoloured clays of the Palaeocene Nacimiento Formation and the Eocene San José Formation.

Primary reference faunas for Puercan (early Palaeocene) and Torrejonian (middle Palaeocene) Land Mammal Ages were collected from the Nacimiento Formation⁷. The Tiffanian Land Mammal Age (late Palaeocene) was based on a fauna collected from sediments in Colorado on the north side of the San Juan Basin. These late Palaeocene sediments are usually included in the San José Formation. On the east side of the basin, the San José Formation contains Wasatchian (early Eocene) mammals¹⁸.

The terrestrial sequence in the San Juan Basin is underlain by marine deposits of the Lewis Shale and the Pictured Cliffs Sandstone formations, which correlate with the middle of the Pierre Shale in the interior North American sequence⁸. This indicates that the lower limit of the San Juan Basin terrestrial sequence is equivalent to late Campanian or early Maastrichtian stages of the European Cretaceous succession.

Our palaeomagnetic section (Fig. 1) begins in Hunter Wash and extends to the head of Barrel Spring Arroyo. The lowest faunal level of the Hunter Wash section is the Hunter Wash local fauna⁹ in the Fruitland Formation. This fauna is represented by bone symbols at the 12 m and 33 m levels in the Hunter Wash section (Fig. 2). The Hunter Wash fauna includes fish, turtles, crocodiles, hadrosaur dinosaurs (*Parasaurolophus*), ceratopsian dinosaurs (*Pentaceratops*), carnosaurs dinosaurs, multituberculate mammals (probably five genera), marsupial mammals (probably two genera), and placental mammals (probably two genera)⁹. The highest Cretaceous faunal level, Ojo Alamo local fauna, occurs in the Ojo Alamo Formation at the 256 m level of the Hunter Wash-Alamo Wash section (at F in Fig. 1). The Ojo Alamo fauna includes fish, turtles, crocodiles, hadrosaur dinosaurs (*Kritosaurus*), ceratopsian dinosaurs, carnosaurs dinosaurs and sauropod dinosaurs (*Alamosaurus*)¹⁵. Unidentified mammals have been

found from the Ojo Alamo local fauna, but descriptions have not been published. The Hunter Wash local fauna may be correlated with the Edmontonian or Lancian Land Mammal Ages^{9,10}.

There has been much confusion surrounding the stratigraphic and age limits of the Ojo Alamo Formation^{9,11}. We accept the definition of Bauer¹², which includes the important Ojo Alamo fauna in the Ojo Alamo Formation^{9,13,14}. We also recognise the last occurrence of dinosaurs within the Ojo Alamo Formation. As emphasised by Baltz *et al.*¹⁵, the upper conglomerate with logs of the Ojo Alamo Formation intertongues with the base of the Nacimiento Formation in Barrel Spring Arroyo.

The lowest stratigraphic occurrence of Palaeocene mammals is the *Ectoconus* zone of Sinclair and Granger¹⁴, shown in our Barrel Spring Arroyo section (Fig. 3). The *Ectoconus* zone (G in Figure 1) and the overlying (by about 15 m) *Taeniolabis* zone (H in Fig. 1) are local divisions of the Puercan Land Mammal Age (early Palaeocene). The *Ectoconus* zone is characterised by the abundance of the peripitychid condylarths *Ectoconus*, *Conacodon*, *Hemithlaeus* and *Anisonchus*, and the absence of the large multituberculate *Taeniolabis*. Fossils are not present continuously between the Ojo Alamo faunal level and the *Ectoconus* zone. Thus, the Cretaceous-Tertiary boundary in this terrestrial sequence occurs between these two faunal levels. Accordingly, the boundary is shown as a vertically striped region in Figs 4, 5 and 6.

Magnetostratigraphy

Three oriented block samples were collected at each of 212 palaeomagnetic sites. The nominal stratigraphic separation between sites was 3 m. Details of the collection technique are discussed in ref. 16. Remanence measurements were accomplished with a cryogenic magnetometer (Superconducting Technology, C-102), and alternating field (AF) demagnetisation was performed with a Schonstedt GSD-1 demagnetiser. The average intensity of the natural remanent magnetism (NRM) was $\sim 10^{-6}$ G. Although AF demagnetisation at peak fields of 200–300 Oe was necessary

Fig. 2 Hunter Wash-Alamo Wash palaeomagnetic data. Site average virtual geomagnetic pole latitude, resulting polarity column and lithological column are plotted against stratigraphic thickness. Shaded regions in polarity column correspond to normal polarity, unshaded to reversed polarity. Palaeomagnetic samples were AF demagnetised in peak field of 200 Oe. Lines at Fruitland-Kirtland contact indicate the gradational nature of the contact. Bone symbols indicate important vertebrate fossil levels. *a*, Conglomeratic sandstone; *b*, sandstone; *c*, siltstone; *d*, coal layer.

to remove secondary components, unambiguous determination of the polarity of the primary depositional remanence was possible for almost all sites. As there is no accepted procedure for data rejection in palaeomagnetic work on sedimentary rocks of this type, we include all results. It should be recognised, however, that large normal components of viscous or chemical remanence can sometimes obscure or replace a primary reversed NRM. Thus, a certain amount of interpretation must take place in obtaining a polarity log from a set of data. Of particular importance in these interpretations are the motions of the NRM vectors during AF demagnetisation and the degree of clustering of the remanence vectors of the three samples at each site. A more complete discussion of the rock-magnetic properties will be published elsewhere.

Figure 2 shows the site average virtual geomagnetic pole (VGP) latitudes in the Hunter Wash-Alamo Wash section. Positive VGP latitudes indicate normal polarity while negative VGP latitudes indicate reversed polarity. But, incomplete removal of secondary normal components generally prevents VGP latitudes of reversed sites from reaching high southerly latitudes. There are two features of this polarity column which require comment. Although the short reversed polarity interval at the 40 m level is based on only two sites, we are confident this magnetozones is real because of the coherent motion of the NRM vectors during AF demagnetisation. There is some inconsistency of the data at the 190 m level near the bottom of a long reversed polarity zone. We place the bottom of this magnetozones at the lowest occurrence of a well-behaved site

with negative VGP latitude. The stratigraphic interval at 190–200 m is coarse siltstone, and we believe it has been remagnetised by the Earth's present field during weathering of the outcrop.

The palaeomagnetic data for sections in Barnum Brown Amphitheater and Barrel Spring Arroyo are shown in Fig. 3. Again, two features of the polarity interpretation require comment. The site with negative VGP latitude in the middle of the normal polarity magnetozones in Barnum Brown Amphitheater was very weakly magnetised and moved toward positive VGP latitude during AF demagnetisation. Because of these observations and our opinion that magnetozones should not be defined by results at a single site, we favour the polarity column shown rather than a more literal interpretation of the data. The site at the 300 m level in Barrel Spring Arroyo consistently moved toward negative VGP latitude during demagnetisation. Thus, the primary NRM component is of reversed polarity.

The stratigraphic correlation required to construct a composite magnetostratigraphic column through the Cretaceous-Tertiary boundary is shown in Fig. 4. The three sections were lithologically correlated in the field by tracing the lower conglomerate layer and overlying clay layers of the Ojo Alamo Formation between the sections. The total lateral distance between the top of the Hunter Wash-Alamo Wash section and the bottom of the Barrel Spring Arroyo section is only 4 km. The beds are easily traced, and there is little chance of error in this lithological correlation. In addition, the bottom of the normal polarity magnetozones at the 260 m level also correlates between sections and confirms the lithological correlation.

Stratigraphers have generally placed an unconformity at the top of the upper conglomerate layer of the Ojo Alamo Formation and have placed the Cretaceous-Tertiary boundary at that unconformity. The Ojo Alamo and overlying Nacimiento Formation, however, intertongue in Barrel Spring Arroyo. Our section avoided the unconformity at the top of the upper conglomerate by sampling the

Fig. 3 Barnum Brown Amphitheater (*b*) and Barrel Spring Arroyo palaeomagnetic data (*a*). Lithological symbols are as in Fig. 2.

Fig. 4 Construction of composite polarity column. Lithological and polarity columns for each of the three sections are shown. Solid line indicates the base of the lower conglomerate layer of the Ojo Alamo Formation, which was used for stratigraphic correlation. Lithological symbols are the same as Fig. 2. Important vertebrate faunal levels are indicated to the right of the composite section.

Nacimiento Formation in the region of the intertonguing. Tertiary mammalian fossils from the *Ectoconus* zone have been recovered in Barrel Spring Arroyo above the intertonguing while dinosaur fossils occur below the intertonguing. Thus, we have sampled through a continuously exposed stratigraphic section with late Cretaceous and early Palaeocene faunas in superpositional order. We assert that the resulting composite magnetostratigraphic column is a virtually complete section through the Cretaceous-Tertiary boundary. The stratigraphic interval within which the Cretaceous-Tertiary boundary must be placed is shown in Fig. 4.

Another possible unconformity is at the base of the lower

conglomerate layer of the Ojo Alamo Formation. This layer is 2-3 m thick and varies from a homogeneous sandstone to a sandstone with basal conglomerate. There are three lines of evidence which indicate that the lower conglomerate does not represent a significant unconformity. First, the Ojo Alamo faunal zone includes the shales above and below the lower conglomerate. Second, in this region there is a very strong lithological similarity of the shale layers above and below the lower conglomerate. In fact, this similarity is so strong that Brown¹³ and Sinclair and Granger¹⁴ included the shales of the upper Kirtland Formation below the lower conglomerate in their definitions of the Ojo Alamo Formation. And third, as shown below,

Fig. 5 Correlation of composite polarity column to marine magnetic anomaly time scale. A portion of the Tarling and Mitchell time scale¹⁷ is shown in *a*, while the composite polarity column from the San Juan Basin is shown in *b*. The San Juan Basin polarity column is scaled to make the length of anomaly 30 match the Tarling and Mitchell time scale¹⁷.

there is a very close similarity between the relative thicknesses of the magnetozones in the composite section from the San Juan Basin with the lengths of corresponding polarity intervals in the marine magnetic anomaly time scale. This similarity suggests that no significant unconformity exists at the base of the lower conglomerate of the Ojo Alamo Formation.

Discussion

Because the lower limit for the age of the Fruitland Formation (as determined from underlying marine formations) is late Campanian to early Maastrichtian, the composite magnetostratigraphic column from the San Juan Basin must be in the late Campanian to Palaeocene interval. Alvarez *et al.*⁸ have shown that late Campanian-early Maastrichtian time corresponds to magnetic anomaly number 33. Thus, none of the magnetozones from the San Juan Basin can be older than anomaly 33. The upper portion of our polarity column is Puercan (early Palaeocene). Evidence from both the magnetic anomaly time scale¹⁷ and magnetostratigraphic studies⁸ indicate that the uppermost magnetozones in our polarity column could not be younger than anomaly 26. Therefore, in attempting to correlate the magnetozones to our composite section with magnetic anomalies, we are constrained to the interval of magnetic anomaly numbers 26-33.

To correlate a magnetostratigraphic section with the anomaly time scale, the section must be of sufficient length and character to allow a unique correlation. A characteristic feature of the marine magnetic anomaly sequence is the very short reversed polarity interval between magnetic anomalies 31 and 30 (Fig. 5). Examination of the polarity sequence in the San Juan Basin reveals the same unusually long normal polarity zone containing one very short reversed polarity zone. In both sequences the long normal polarity interval is followed by more frequent, evenly spaced reversals in the Lower Tertiary. Given the constraints outlined above, the sequence of magnetozones in our composite section contains sufficient character to allow correlation with the magnetic anomaly time scale. The resulting correlation (Fig. 5) indicates that the normal polarity magnetozones in the San Juan Basin section correspond to magnetic anomalies 27 to 31. No other correlation with the magnetic anomaly time scale can be made without assuming very large and rapid changes in sedimentation rate.

Figures 4 and 5 demonstrate the position of the Cretaceous-Tertiary boundary within our stratigraphic sequence. The highest occurrence of in-place dinosaur fossils is toward the top (young side) of anomaly 29 while the lowest Palaeocene mammal fossils are found near the top of the succeeding reversed interval between anomalies 28 and 29. Therefore, the Cretaceous-Tertiary boundary in this North American terrestrial sedimentary sequence occurs in the interval between the middle of anomaly 29 and the beginning of anomaly 28.

Fig. 6 Correlation of magnetozones in *b*, the San Juan Basin and *a*, the marine Scaglia Rossa Limestone of Gubbio, Italy⁶. Only the upper portion of the polarity column from Gubbio, Italy, is shown. The polarity columns were scaled so that the lengths of anomaly 30 are equal.

A correlation of the Gubbio, Italy section with the San Juan Basin section is shown in Fig. 6. This correlation is a graphic illustration of the potential of magnetostratigraphy. Through the intermediate step of correlating these sections to the magnetic anomaly time scale, a very accurate stratigraphic correlation between a marine sequence in Italy and a terrestrial sequence in western North America has been accomplished.

Our data show that the Cretaceous-Tertiary boundary in marine and terrestrial rocks is not synchronous. The Cretaceous-Tertiary boundary, recognised by vertebrate fossils in the San Juan Basin, is younger than the Cretaceous-Tertiary boundary, as recognised by marine invertebrate fossils. The amount of non-synchronicity is small, however. The age difference between the beginnings of anomalies 29 and 28 is of the order of 1.5 Myr (ref. 17). Thus, even the maximum time difference between the Cretaceous-Tertiary boundary at the Gubbio, Italy section and at the San Juan Basin section is probably less than 1.5 Myr. The minimum time difference may be as little as 0.5 Myr. Considering the vast geologic time distance from which we are viewing this event, the relative degree of synchronicity is remarkable.

We thank G. G. Simpson for helpful advice. Many of the magnetic sample preparations and measurements were done by S. L. Bressler and L. H. Taylor. This work was supported by the US NSF, the Research Corporation and the state of Arizona.

A 2.6 Myr K/Ar age has been derived for a primary unworked tuff high in the hominid-bearing Hadar Formation (Kada Hadar Member), stratigraphically above all the important fossil finds. A 2.6 Myr fission track age has been derived on zircons from this tuff. New K/Ar results on the Kadada Moumou basalt (Sidi Hakoma Member) suggest a 3.0 Myr age. Preliminary interpretation of a detailed continuous palaeomagnetic section through the formation indicates the existence of persistent normal and reversed sequences. With the radiometric age control this magnetic sequence appears to correlate with the Gauss Epoch. These initial results imply the fossil-rich Hadar Formation spans from somewhat older than 3.1 Myr to somewhat younger than 2.6 Myr.

origin with a rich vertebrate fauna including relatively abundant and excellently preserved hominid material³⁻⁵. In this paper, we present new geochronologic and palaeomagnetic data pertinent to establishing the age of the formation. A geologic column for the Hadar Formation, which represents the area exposed along the Sidi Hakoma and Kada Hadar tributaries north of the Awash River, is shown as section A (Fig. 1). Details of the stratigraphy are presented elsewhere^{1,2}.

Geochronology of Bouroukie Tuffs

Three tuffs have been newly found in the Kada Hadar Member (KHM), which is the uppermost member of the Hadar Formation. We have named these tuffs BKT₁, BKT₂ and BKT₃, from oldest to youngest (Fig. 1), which are well exposed in the Bouroukie tributary to the Kada Hadar drainage. BKT₁ is a 15-cm thick chalky white clay typical of most of the Hadar Tuffs and probably represents completely altered glass ash. BKT₃ is a 75-cm thick buff-coloured glass shard ash with numerous tubular fillings presumed to be root casts. BKT₂ is at present the most

THE well-exposed Plio-Pleistocene Hadar Formation^{1,2} in the central Afar Depression is of lacustrine and lake-margin

Fig. 1 Palaeomagnetic log of the Hadar Formation. Location of the Gauss Normal Epoch containing the Mammoth and Kaena Reverse Events is shown with reference to three recent versions of the geomagnetic polarity time scale. The important hominid levels are indicated, including the australopithecine skeleton 'Lucy' and the Homo family (site 333). Also shown are all of the tuffs and the basalt and the dates for BKT₂ and the basalt. The members of the Hadar Formation are from the bottom up: Basal Member (BM); Sidi Hakoma Member (SH); Denen Dora Member (DD); and Kada Hadar Member (KH). Legend for the generalised geologic inset map: 1, recent Awash River alluvium and forest; 2, Pleistocene capping gravels; 3, Hadar Formation; 4, Kadada Moumou basalt; and 5, location of palaeomagnetic sections. In palaeomagnetic section B, the open circles schematically represent reversed section and the solid circles represent section of normal polarity.

promising of all the tuffs in the Hadar Formation for geochronology. It consists of two beds separated by 1 m of brown silty clay. The lower bed is a 10–15 cm thick pale yellow crystal-bearing tuff. It is similar to the lower part of the 40-cm thick upper bed on which our geochronology has focused.

The petrology of the upper BKT₂ tuff bed indicates it is of primary pyroclastic origin, uncontaminated by older sediment. The bed has been sharply stratified into two layers by primary aeolian differentiation during the explosive eruption. The upper layer making up two-thirds of this bed is a porous black and white fine lapilli lithic tuff consisting entirely of 1–4 mm grains and granules of rock fragments partially cemented by calcite. The lower layer making up one-third of the bed is a pale yellow crystal and lithic tuff which provided anorthoclase for K/Ar analyses and zircon for the fission-track dating.

The upper lithic tuff layer consists of 65% smaller grains of a brown glass obsidian that is very vesicular (30–50% holes), and 35% larger grains and granules of white (clear) pumice with a spindle-like alignment of glass fibrilles. A gas-rich eruption that became explosive is indicated by these grains, and their coarseness suggests the source was one of the nearer-by Afar acidic volcanoes. Very fine grained basalt (?) forms uncommon inclusions in the obsidian. Both obsidian and pumice have large uncommon phenocrysts of anorthoclase and pyroxene similar to the crystals we will describe from the lower layer. The preservation of fragile broken bubble projections on the obsidian fragments indicates that very little or no rolling transportation occurred. That there was no sedimentary reworking is also indicated by the preservation of the primary aeolian differentiation layering, and the complete lack of any matrix of finer normal density grains for the lower density framework grains of vesicular obsidian and pumice.

The lower one-third layer obtains its pale colour and friability because of the entirely clay-altered 0.5–1 mm grains of collapsed pumice which make up 70% of the layer. Five per cent of the layer is fragments of a magnetite-rich non-vesicular brown obsidian and lesser amounts of a magnetite-rich fine-grained basalt (?). The remaining 25% of the layer is euhedral to subhedral crystals of an exceedingly simple volcanic mineral assemblage: about 24% of a very low-K₂O anorthoclase; 1% green augite rimmed by fibrous amphibole (?); and common magnetite and zircon. All of these four are cogenetic as indicated by the distinctive occurrence of the magnetite as euhedral octahedrons in isolated grains and as very frequent inclusions in each of the other three minerals, and by the occurrence of binary combinations among all the minerals. In addition, the minerals are cogenetic with the obsidian and pumice rock fragments in the upper layer because of their occurrence there as large phenocrysts. It is unlikely the crystals were derived by explosion of a pre-existing rock because all grains are free of any adhering rock matrix. The anorthoclase appears milky under binocular microscope, but clear and unaltered in thin section. It is optically unusual for a potassium feldspar in displaying to various degrees the three major simple feldspar twins (albite, pericline and carlsbad) as well as being untwinned. For example, carlsbad twinned grains occur with one half albite twinned and the other untwinned and optically anorthoclase. Because some grains only display albite twinning, the presence of some plagioclase cannot be ruled out. Staining of the thin section for K₂O, however, developed an equally light measles-like stain on all grains independent of the twinning characteristics, indicating each of the grains is of the same moderately low K₂O content. Additionally suggestive that only one feldspar is present comes from K₂O analyses of seven finely resolved density fractions of the total feldspar. The total range in K₂O was only 1.70–2.00%, with no variation in the four lightest sinks. Thus, no high K₂O feldspar phase exists

in the rock and probably no plagioclase, just the single low-K₂O anorthoclase.

Because of the simple and distinctive mineral assemblage, any extraneous sedimentary components in the lower layer should be apparent. The complete absence of quartz, high-K₂O feldspar, and any variety of rock fragments, and the probable absence of plagioclase, sensitively indicates no admixture of older sedimentary grains has occurred. Together the mineralogy, texture and structure provide abundant evidence that the BKT₂ upper tuff bed is of primary pyroclastic origin with crystals formed at the time of eruption and uncontaminated by older material thereafter.

Four repeat potassium and argon measurements on splits of the same unpicked separate of anorthoclase yield consistent analytically precise ages of 2.65 ± 0.05 Myr (80% radiogenic argon) (Table 1). We report the CWRU laboratory average of 14 measurements of the USGS LP6 Biotite interlaboratory standard because the tracer constant for our bulb-pipette tracer system is presently assigned a value that causes all our age measurements to be 3.5% low in comparison with the average of other laboratories which have run this standard (J. C. Engels, personal communication). Correcting to these other laboratories would raise the 2.6 Myr age to 2.7 Myr. This discrepancy is being evaluated by measuring absolute atmospheric argon standards.

The zircon, which is a common accessory in this sample, has a large range in grain size, from 30 to 120 μ m. All sizes uniformly have a light reddish cast and are euhedral pyramidally terminated prisms. The length to width ratio is variable from 2–10, with stout forms predominant. Eleven grains of the +140 mesh fraction were dated by one of us (C.W.N.) by counting fossil and induced fission tracks (Table 2). The average fission track age of the eleven grains is 2.58 Myr with a standard deviation of ± 0.23 Myr.

Because all of the Hadar Formation fauna recovered so far is stratigraphically below BKT₂, these concordant K/Ar and zircon fission track ages, and the unlikelihood that the tuff is contaminated, indicate that the fauna is older than 2.6 Myr.

Geochronology of Kadada Moumou basalt

The stratigraphic position of the Kadada Moumou basalt flow at the eastern edge of the Hadar site is now established within the upper part of the Sidi Hakoma Member. The Kadada Moumou subplateau is upheld by the 1–4 m thick resistant basalt flow which is capped unconformably by mid-Pleistocene (?) gravels and sands with Acheulean artifacts⁶. Near the northwest end of the basalt some grey mudstone above the basalt may represent the only Hadar Formation sediment not stripped by erosion from above the basalt. The basalt is 70 m above the Sidi Hakoma Tuff (SHT) which forms the base of the Sidi Hakoma Member. The basalt was erupted on a gentle erosional surface of subdued topography with local relief up to about 10 m. The northwest end of exposure of the basalt probably represents a slightly eroded flow front. A cross-section of a large 10 m deep palaeo-channel or palaeo-embayment is exposed along this flow front. We have established that the channel is filled with Hadar-age sand beds which post-date the basalt and which can be related to the overlying Hadar sequence. The channel fill sand beds have original dips parallel to the approximate 20° slope leading downward from the basalt. The initial sand bed in the channel contains numerous boulders and cobbles of the vesicular basalt and thus post-dates the basalt. These channel-fill sands are of undoubted Hadar Formation age because they contain abundant Hadar fauna. One basalt boulder in the basal sand of the channel was found within the metre-wide carapace of a fossil turtle (discovered by B. T. Gray). Conformably above the channel fill is a distinctive extensive sand horizon with abundant root casts. It can be traced from the basalt front directly

into the main Hadar sequence, where it lies 20 m below the triple tuff marker horizon that is the top of the Sidi Hakoma Member (SHM) (Fig. 1). This marker has been walked out to the main fossil bearing localities in the Kada Hadar drainage. Thus, the basalt erupted on an erosional surface that is probably minor within the Sidi Hakoma Member at the eastern edge of the Hadar site. In the Kadada Moumou area, it is located 70 m above the base and 20 m below the top of the member. Further west in the main part of the Hadar site the Sidi Hakoma Member has a total thickness of only 60 m (Section A) compared to the 90 m in the east. A more detailed correlation of the

The average of six K/Ar analyses of three geographic samples of the shiny black variety is 3.0 Myr with an average deviation of ± 0.06 Myr (Table 1), including our two previously reported results¹. In contrast, one sample of the more altered sugary-textured variety gives an age of 2.65 Myr (two analyses) and another sample, which is a little more altered, an age of 2.50 Myr. Each individual analysis of the Kadada Moumou basalt has an estimated uncertainty of ± 0.2 Myr, because the extracted argon was only 10–20% radiogenic.

A key factor in interpreting the K/Ar discrepancy between the two varieties is secondary mineralisation, which

basalt position within this thinner section to the west is suggested in the discussion on magnetostratigraphy (Fig. 1).

Several K/Ar results on the basalt fall into two groups which correlate with the two subtle varieties of the flow selected from fresh cores of large talus blocks. These varieties probably represent a different vertical position in the flow not yet observed. One variety is a relatively unaltered dark black rock breaking with a smooth surface compared to a dark grey more granular or sugary-surfaced variety which thin section study indicates is relatively more altered. Both types consist of fine-grained plagioclase, augite, magnetite and minor olivine in a cryptocrystalline glassy matrix. The dark grey granular variety is coarser grained (0.2–0.4 mm compared with 0.15 mm), and contains much less of the cryptocrystalline matrix (10% compared with 35%) than the smooth black variety. The smooth black variety largely obtains its character from this abundant cryptocrystalline matrix, charged with magnetite dust.

occurs in two ways: (1) a filling of cavities, which occurs in both varieties of basalt and is interpreted not to have affected the age measurement; and (2) a yellowish clay alteration of the glassy matrix which affects only the grey variety and could well have caused argon loss. As regards the secondary filling, both varieties have a diktytaxitic texture (angular interstitial cavities) with the smaller cavities filled with a yellowish clay (?) and larger cavities lined with the clay concentric about a coarse calcite filling. This secondary filling is the same observed in the abundant vesicles at the top of the flow which may be empty, lined with clay, or lined with clay around calcite. A complete gradation can be observed in the same outcrop between samples with only fine angular interstitial cavities and samples with only normal rounded vesicles. As regards the secondary alteration, which affects only the grey variety of basalt, about 10% of the cryptocrystalline glassy matrix areas of KM-3-74, and about 50% of the matrix areas in

KM-1-74, have interior regions which have altered to a yellowish orange clay (?). The altered zone cuts across and includes relict magnetite grains. Because of the relatively small proportion of glassy matrix in the grey variety (10%), a significant portion of the rock's K_2O can be expected to have been residually concentrated in the glassy phase; if the alteration occurred much later than the eruption, it would have resulted in argon loss and reduced the age measurement. Because the shiny black variety has no alteration of its large amount of glassy matrix (35%), and because there is an indication that the smaller amount of clay-like material in this rock is not an alteration but a secondary filling, we interpret its K/Ar system to be unaltered. To be conservative, its 3.0 Myr age should be regarded as a minimum age because a coexisting variety of the flow, which has endured a similar history, has demonstrably lost argon compared to it.

Magneto-stratigraphy

Studies at East Turkana (formerly Lake Rudolf)⁷ and at Omo⁸ have demonstrated the usefulness of magneto-stratigraphy as a geochronological tool in the terrestrial Plio-Pleistocene sediments of East Africa. One of us (T.J.S.)

been deposited during a time of reversed polarity, with the irregularity resulting from partial remagnetisation during exposure to the present normal polarity. Until we are able to establish the precision of the boundaries by more widespread sampling, the uncertainty in the stratigraphic position of the polarity transitions is assumed to be within 10 m. Figure 1 shows the location of these polarity transitions in sections A and B.

Taken together with the absolute age control, provided primarily by the 2.6-Myr BKT₂ tuff and secondarily by the 3.0-Myr basalt age, the dominantly normal palaeomagnetic stratigraphy of the Hadar Formation is interpreted to be of Gauss Epoch age. The two reversed sequences would represent the well-documented Mammoth and Kaena Events which took place about 3.0–3.1 Myr ago and 2.8–2.9 Myr ago, respectively, as determined by numerous geochronologic studies elsewhere in the world^{9–11}. This correlation with the world-wide reversal scale is shown in Fig. 1.

The palaeomagnetic results of the 30 samples collected the previous field season from three parts of the Hadar Formation¹ are perfectly in accord with the new detailed stratigraphy presented here. One problem arises in correlating partial section B of the Ounda Hadar area with

Table 2 Fission track dating results for BKT₂ (tuff)

* Mean $\pm$ 1 s.d.

has started a detailed study of the palaeomagnetism of the Hadar Formation. The preliminary results suggest that a magnetic stratigraphy is retained which can be correlated with the palaeomagnetic polarity reversal time scale. So far only one complete section of the formation has been taken, sampling approximately every half metre. This section (section A, Fig. 1) is in the Sidi Hakoma and Kada Hadar drainage, where most of the fossil localities of the Hadar site occur. In addition, a partial section (section B, Fig. 1) with irregularly spaced samples from 1–4 m apart has also been measured in the Ounda Hadar drainage, including the basalt flow. A total of 400 samples were collected.

All the samples were subjected to progressive alternating field (A.F.) demagnetisation in order to determine the direction and stability of their remnant magnetism. The details of the magnetic behaviour of individual samples will be presented after more sections are completed and only a summary is reported here. The major result is that after 200 Oe of A.F. demagnetisation, the remnant magnetism of individual samples falls into three sequences of very uniform normal polarity, and two sequences of predominantly reversed samples with intermixed samples of random polarity. Every tenth sample of section A (about every 5 m) was subjected to further progressive demagnetisation up to 1,000 Oe. All of these further demagnetised samples in the three normal zones maintained their persistent normal polarity with directions close to north. The randomly interspersed intermediate samples from the dominantly reversed sequences which were defined at 200 Oe of demagnetisation, generally revealed a reversed or more nearly reversed remnant direction on further demagnetisation. The reversed samples in these sequences maintained their reversed polarity. Thus, the higher field demagnetisation enhanced the contrast evident between the two kinds of sequences. We interpret the two sequences with dominantly reversed remnant magnetisation to have

Section A, because 40 m of reversed sediment occur below the ostracod marker bed in Section B and only 10 m occur below this marker in Section A. The thickness of the Sidi Hakoma Member in Section B is 90 m compared to only 60 m in Section A. The present magneto-stratigraphy suggests that most of this east to west variation in thickness of the Sidi Hakoma Member can be ascribed to the very upper part of the member. To what extent this thickness variation is due to varying rates of deposition or to unconformities is not known.

If interpretation of the age framework of the Hadar Formation continues to be substantiated, then more detailed palaeomagnetic studies may allow for additional precision in the stratigraphy, palaeogeography and faunal evolution at the Hadar site. At present, the geochronology and palaeomagnetism suggest for the Hadar Formation and its rich fauna a Gauss Epoch age that spanned from somewhat more than 3.1 Myr ago to somewhat less than 2.6 Myr ago.

We thank Robert Sedivy for assistance with K/Ar measurements. This work was supported by the US NSF, C.N.R.S., the National Geographic Society, the L.S.B. Leakey Foundation and OTAN. J.L.A., T.J.S., M.T., D.C.J., J.J.T. and R.C.W. are members of the International Afar Research Expedition.

letters to nature

The rings of Uranus

At least five rings encircle the planet Uranus—as indicated by five brief occultations of the star SAO 158687 that occurred both before and after its occultation by Uranus on 10 March 1977. We observed these events with our three-channel occultation photometer¹, attached to the 91-cm telescope aboard the Kuiper Airborne Observatory (KAO). Both Uranus and the star were contained within a focal plane aperture whose diameter, projected onto the sky, was 46 arc s. A beamsplitter and focal plane television system allowed us to monitor the position of the image in this aperture simultaneously with the photometric measurements. The wavelengths of the three photometric channels used were chosen to yield favourable ratios of starlight to Uranus light² and are given in Table 1. For each channel a cooled photomultiplier (RCA C 31034), connected to a photon-counting system, was used as a detector. The data were recorded as a continuous series of 10-ms integrations of photon counts, and a strip chart recorder displayed the signals from our channels 2 and 3 so that we could monitor the progress of the occultation in real time.

Table 1 Centre wavelengths of filters

Channel no.	Centre wavelength (Å)	Passband (Å)	Star counts* Star+background counts
1	6190	80	0.15
2	7280	200	0.32
3	8520	210	0.42

*These ratios were obtained from the observed signal levels.

The final predictions^{3,4} for the occultation indicated that the northern limit of the occultation would pass south of northern Australia, but its precise location was uncertain. Accordingly, the course of the airborne observatory was planned to be as far south as possible. At about 20 h 00 min UT, the KAO assumed a course that allowed tracking on Uranus, and continuous data recording began at 20 h 05 min 40 s UT. A sharp decrease in the recorded light intensity occurred at 20 h 11 min 43 s UT and several seconds elapsed before the signal returned to its original level. This event was followed by several others of shorter duration within the next few minutes. The cause of these events was initially thought to be momentary failures of the telescope tracking system, but careful examination of the Uranus image on the television monitor showed the tracking to be steady. Another cause considered was thin cloud, but at our altitude of 41,000 feet this was unlikely. The infrared water vapour monitor on board the KAO confirmed that no clouds were present. We concluded that the drops in intensity were definitely light lost from the star, since the dips had the proper ratios at different wavelengths (see Table 1). For this case the only plausible cause of these brief intensity dips would be occultations by small bodies, probably associated with Uranus.

About 30 min later, Uranus occulted the star. The occultation lasted about 25 min and had a midtime of 21 h 06 min UT, in good agreement with the predictions based on the

position of the star and Uranus determined by Franz and Wasserman⁵. We then continued our observations in expectation of recording more brief occultations. Five such events were recorded before the data recording was stopped at 22 h 17 min 40 s UT, due to the high level of morning twilight. Similar brief occultations of SAO 158687 when Uranus was near it were also observed by Millis, Birch and Trout at Perth^{3,6}; by Bhattacharyya and Kuppuswamy at Kavalur^{5,6} and by Churms⁶ at Cape Town.

Table 2 contains the midtimes and approximate durations of the brief occultations that we observed. The approximate location of the Airborne Observatory was lat. 50°20'S, long. 82°11'E for the pre-immersion events and lat. 50°21'S, long. 101°19'E for the post-emersion events. In Fig. 1 we have plotted our light-curves (channel 2) for both sets of events after averaging the data over intervals of 0.5 s. The intensity parameter $\phi(t)$ equals 1.0 for the unocculted intensity of SAO 158687 and 0.0 when the star is totally occulted. We have not attempted to remove from these data possible long-term drifts in sky background light and instrumental gain, which could amount to a few per cent. The slow rise in signal level starting at 21 h 52 min UT is caused by morning twilight.

We assumed that the bodies causing the occultations lie in the satellite orbit plane of Uranus and computed their distance from the centre of Uranus. The angle between the line of sight and the normal to the satellite orbit plane was 36.6°. In this computation, the radius of Uranus was set equal to 25,900 km (ref. 8). Then the chord length observed when Uranus occulted the star⁵ was used to fix the position of Uranus relative to the star. The motion of the KAO was not taken into account in this calculation, however, thus introducing systematic errors of several hundred km, which can ultimately be eliminated. But, since the groups of events occurred at approximately equal times before and after the Uranus occultation itself, the errors in the relative distances between the immersion and emersion events should be less than 100 km.

Table 2 Short occultation events

Pre-immersion events		Post-emersion events	
Midtime (UT) h min s	Approximate duration (s)	Midtime (UT) h min s	Approximate duration (s)
20:11:46	7	21:45:52	1
20:16:03	1	21:47:06	1
20:16:58	1	21:49:45	1
20:19:34	1	21:50:39	1
20:20:55	1	21:54:06	3

The striking impression from Fig. 1 is that the occultations in both groups of events occur at corresponding distances from Uranus. Moreover, the amplitudes and durations of the corresponding events are similar. We feel this is strong evidence that the occultations were caused by five narrow rings that encircle the planet, rather than random occultations caused by small satellites within a broad belt as we and the Lowell group had originally suggested^{3,9}. We have tentatively labelled the rings with the letters α – ϵ , beginning with the ring closest to Uranus.

Fig. 1 Light curves (channel 2) showing the five brief occultations observed both before and after the occultation of SAO 158687 by Uranus on 10 March 1977. The intensity scale $\phi(t)$, has been normalised to the unocculted intensity of SAO 158687, and on this scale the amount of starlight occulted ranges from about 0.4 (β and γ events) to about 0.9 (ϵ events) of the total. An approximate distance scale has been computed under the assumption that the bodies causing the occultations lie in the orbit plane of the Uranus satellites. The equal number and symmetry of the occultations suggest that four narrow rings (~ 10 km wide) and a broader ring of variable thickness (ring ϵ , 50–100 km) encircle Uranus. Beginning at 21 h 52 min UT, the start of twilight caused a slow rise in the signal level.

Since the KAO data was the only set reported to contain both the pre-immersion and post-emersion occultation events, we were in a unique position to infer the presence of narrow rings. Subsequent calculations by Marsden⁷ showed that the times of the events observed at Perth and Cape Town led to distances from Uranus, within its satellite orbit plane, that closely agreed with those obtained from our data. Hence the interpretation that these events were caused by narrow rings encircling Uranus has already survived a stringent observational test. (We note a ~ 800 km discrepancy between Marsden's distance scale and our own that arises from different assumptions for our respective calculations. But, the distances of corresponding pre-immersion and post-emersion events are nearly equal for either calculation.)

Our light curves also contain other brief occultations, significantly shallower than the ring α - ϵ events, and are probably caused by additional material within the ring system of Uranus. One example is the decrease in signal that occurs shortly before the ring γ occultation on emersion (see Fig. 1), and there is some indication in our data of similar occultations that correspond to the latest two events reported by Millis, Wasserman and Birch⁷. Our figure does not include this time interval. As yet we have not searched our data for long, shallow occultation features that would correspond to broad rings of low optical depth.

Ring ϵ seems markedly different from the other four in

several respects. It causes much deeper occultations of the star that last longer, but are of unequal duration (Table 2) for the two sections of ring ϵ probed by our observations. Also the times of the occultations by ring ϵ do not agree with its being circular and in the plane of the satellite orbits.

Possibly ring ϵ is elliptical, or has an orbit plane inclined to that of the satellites; it may be that what we have identified as a single ring is actually two incomplete rings. From our data alone, we cannot confirm or rule out any of these explanations, and as yet cannot suggest a more sophisticated model to explain the times and durations of the occultations caused by this ring.

To estimate the width of the rings, we note that the Uranus shadow velocity was 12 km s^{-1} and use the occultation durations given in Table 2. These values yield a width of ~ 12 km, projected onto the plane perpendicular to our line of sight, for rings $\alpha, \beta, \gamma, \delta$; ~ 85 km for the immersion section of ring ϵ ; and ~ 35 km for the emersion section of ring ϵ . We emphasise that these widths are only approximate, since we did not include (1) the convolution broadening of the observed occultation durations caused by the projected diameter (~ 6 km; see ref. 10) of the star at Uranus; (2) diffraction effects (Fresnel scale, $\sqrt{\lambda R} \sim 1.5$ km); (3) the projection angle between the apparent stellar velocity and the orientation of the ring; and (4) effects caused by the orbital motion of the rings, with a velocity of 11 km s^{-1} , that would be important if the optical depth of the rings is not uniform on scales comparable to, and larger than, the projected stellar diameter.

Since none of the rings caused a total occultation of the star, we think they are composed of numerous bodies, with sizes of < 6 km (the projected diameter of the star), rather than larger objects. There are no obvious differences in the structure of the occultations at the different wavelengths that we observed. Such differences would be indicative of diffraction effects and/or wavelength dependent extinction and perhaps provide an important clue to the nature of the occulting material. We plan to pursue this analysis further.

Valuable observations of future occultations by the rings can be obtained for stars significantly fainter than SAO 158687 ($m_v \sim +9.5$; see ref. 10); the precise limiting magnitude will depend on the spectral type of the star and the aperture of the available telescope². Since these occultations need not involve an occultation by Uranus itself, we suggest that present lists of appulses involving Uranus be reviewed in search of those that could result in occultations by the rings. Also, future occultation predictions for Jupiter, Uranus, and Neptune should include information about the apparent path of the star relative to the satellite orbit planes of these planets. The possibility that Jupiter has rings comprised of 'rocky' bodies cannot at present be excluded¹¹. Saturn's rings may contain narrow components, of much higher optical depth than the average, akin to the rings of Uranus. An opportunity to check this possibility, but with coarser spatial resolution than the present measurements for Uranus, occurs in October 1977 and January 1978 when the satellite Iapetus is eclipsed by Saturn and its rings¹².

Possibly the Uranus ring system can be detected through direct photography. If the rings have the same albedo as the cloud tops of Uranus, their combined integrated intensity should be $\sim 0.7\%$ of that of the Uranus disk. This ratio should be substantially more favourable for wavelengths within the methane absorption bands².

The distances between the various rings pose an interesting theoretical problem that can possibly be explained by resonances with orbits of the known satellites and will perhaps require the inference of another satellite. All five rings are well within the Roche limit, which is about 70,000 km for Uranus.

The fundamental question of why rings were unique to

Saturn has been posed many times in the past¹¹, and the particular case of why Uranus was thought to have no rings has been addressed also¹². We now ask, why are the rings of Uranus so narrow—in contrast to the broad rings that surround Saturn? The possibility of 'very small bodies, similar to the asteroids' being found between the orbit of the inner-most satellite Miranda and Uranus itself has been mentioned by Alfvén and Arrhenius¹³; the narrow rings may well be a manifestation of the 'jet streams', discussed at length by the same authors¹³. The theoretical basis for jet streams has not won general acceptance¹⁶, however, and we expect that alternative theories for the narrow rings will become available soon.

We thank the staff of the Kuiper Airborne Observatory, headed by Carl Gillespie, for assistance and acknowledge our close association with R. L. Millis and L. H. Wasserman of Lowell Observatory in planning our respective observations and in comparing results. Also, we are grateful for discussions with B. Marsden, J. Veverka, D. Hunten, G. E. Taylor, W. B. Hubbard and Carl Sagan that generally contributed to the success of this project. This work was supported by NASA and E.D. is supported in part by an Allen Seymour Olmsted Fellowship.

Note added in proof: W. B. Hubbard has reported that three ring occultations were observed by B. Zellner at Perth Observatory.¹⁷

Detection of rings around Uranus

AN occultation of the ninth-magnitude star SAO 158687 by Uranus on 10 March 1977 was predicted by Gordon Taylor¹ in 1973. Although the original prediction indicated that the occultation would be widely visible from land masses surrounding the Indian Ocean, subsequent work by Franz and Wasserman (at Lowell Observatory) showed that ground-based observations would be possible only from southern Africa and possibly from southwestern Australia². In view of the wealth of new information about Uranus which could be derived from photometric observations of this event³, we decided to attempt observations using the 61-cm Planetary Patrol telescope at Perth Observatory near Bickley, Western Australia. In fact, an occultation of the star by Uranus itself did not occur at Perth. Partial occultations of SAO 158687 by a series of rings around the planet were observed and are described here.

Measurements were made using a conventional single-channel photometer equipped with an RCA C31034B photomultiplier. The observations were made through an

interference filter centred at 8524 Å with a width of 212 Å (FWHM). Since this filter coincides with a strong methane band in the spectrum of Uranus, the signal from SAO 158687 relative to that from Uranus was greatly enhanced³. An identical filter was used by Elliot *et al.* in one channel of their multi-colour observations of this occultation⁴. The signal from the photomultiplier was amplified by a Kiethley Model 301 operational amplifier and displayed on a strip-chart recorder. The response time of this system for a full-scale deflection is less than 0.5 s. In addition, the signal from the amplifier was fed to a voltage-to-frequency converter whose output was recorded on magnetic tape. This feature provides for digital output of the data at high time resolution, but its recording capacity is limited to 45 min.

During the observations, Uranus was centred in a 28-arc s diameter aperture. Measurements started at 20 h 00 min 00 s UT and continued well into morning twilight with brief interruptions at 5-min intervals for recentering the planet. It is clear from these observations that an occultation of SAO 158687 by Uranus itself did not occur at Perth. But, between 20 h 10 min and 20 h 24 min—well before the predicted time of the occultation of the star by Uranus and before the digital recording system had been turned on—five brief partial occultations of SAO 158687 were detected with the chart recorder. The midtimes, durations, and depths (total occultation=1.0) of these events are listed in Table 1. We estimate a maximum uncertainty in the listed midtimes of ± 0.2 s.

Table 1 Occultations of SAO 158687

Event	UT h min s	Duration (s)	Depth
1	20 10 33.2	8.2	0.94–0.52
2	20 15 58.7	0.7	0.42
3	20 18 44.1	1.5	0.38
4	20 23 19.0	1.0	0.21
5	20 23 42.4	0.9	0.29

Several similar partial occultations were observed by Elliot *et al.*, observing aboard the Kuiper Airborne Observatory about 2,000 km south-southwest of Perth, by Churms at Capetown and by Bhattacharyya and Kuppaswamy at Kavalur^{5,6}. A cursory comparison of the aircraft data and the Perth observations a few hours after the occultations led to a preliminary conclusion by both groups of investigators that several individual members of a satellite belt around Uranus had been detected⁵. The Cornell investigators subsequently discovered, however, that the occultations which they observed prior to the Uranus occultation were very nearly mirror images in time of those which they observed following the Uranus occultation. It was then concluded that the occulting bodies were five narrow circular rings in the equatorial plane of Uranus^{4,6}. These rings have been designated α , β , γ , δ , and ϵ , starting with the innermost ring. The 61-cm Perth observations support this interpretation. If we predict when occultations by these five rings would have occurred at Perth, we find that event number 1 in Table 1 corresponds to the ϵ ring, event 2 corresponds to the γ ring, and event 3 corresponds to the β ring. We did not observe the occultations by rings α and δ at Perth because at their predicted times of occurrence, the observations had been interrupted for about 10 s to recentre the planet. Events 4 and 5, although shallower than the other occultations, are well above the noise level of our observations. It is not yet clear whether these events are present in the observations of other observers, so the nature of the occulting objects is uncertain in these two cases. If these objects are

Fig. 1 The occultation light curve observed at Perth for the ϵ ring. The number of seconds past 20 h 10 min 00s is given along the abscissa with time increasing to the left. The sharp drop in signal following the occultation resulted from an interruption of the observations to check the centering of the planet in the photometer's entrance aperture. The contributions to the total signal by SAO 158687 and Uranus are indicated by *a* and *b* respectively.

in circular orbits in the equatorial plane, their orbital radii are approximately 42,000 and 42,250 km.

The Perth light curve of the occultation by the ϵ ring is shown in Fig. 1. This is by far the longest of the five occultations observed at Perth, with the ring extending for a distance of about 90 km along the occultation chord. The abruptness with which the occultation begins and ends indicates that the ring has rather sharp boundaries. Substantial variation in transparency across the ring is seen. Since at no point was the star totally obscured, it can be concluded that the majority of the individual particles in the ring have dimensions smaller than the apparent diameter of the star at Uranus, which we estimate to have been about 4 km. The maximum obscuration which we observed corresponds to an optical thickness of about 2.3,

Fig. 2 The occultation light curve observed at Perth for the γ ring. The number of seconds past 20 h 15 min 00s is given along the abscissa with time increasing to the left. The contributions to the total signal by SAO 158687 and Uranus are indicated by *A* and *B* respectively.

which is substantially larger than that of the B ring of Saturn⁷.

Figure 2 shows the occultation light curve observed at Perth for the γ ring. The very brief duration of this occultation implies that the width of the ring is no more than a few kilometres. The other three occultation light curves observed at Perth are very similar in character to that produced by the γ ring.

Further occultation observations have been reported^{8,9}.

We thank D. Trout for technical assistance. This research was supported by NASA. The planning of these observations was facilitated by the cooperation of J. L. Elliot and his associates at Cornell University.

A new satellite of Uranus

WHILE observing the occultation of the star SAO 158687 by Uranus on 10 March 1977 we came across an unexpected event suggesting the existence of a hitherto unknown satellite of the planet. The observations were carried out at the Kavalur Observatory (lat. 12° 34' 32" N; long 78° 49' 54" E) using a near infrared photometer consisting of a refrigerated EMI 9558B phototube and Kodak Wratten 89B filter attached to the Cassegrain focus of the 102-cm telescope. The individual deflections due to the star and the planet were measured during the previous night, as well as a few hours before the predicted instant of occultation. A 16-arc s diaphragm was used during occultation, whereby the planet and the star could be conveniently contained for several hours around the epoch of occultation. Guiding and monitoring of the objects were done through the 20-cm guide telescope, with periodic checking of the centering in the main telescope. As indicated by the prediction¹, we expected only a grazing occultation to be visible at Kavalur, resulting in a slight diminution in the intensity of starlight owing to the extinction effect by differential refraction in the outer layers of the planet's atmosphere². A very shallow depression of 0.046 magnitudes in the light of SAO 158687 was indeed observed.

About 40 min before the midpoint of this dip we observed at 20 h 19 min 38 s UT a sharp drop in the light curve which lasted 8.9 s (Fig. 1). The phenomenon was visually observed in the guide telescope also, as a sudden disappearance of the star in the field of view followed by an equally sudden reappearance, a few seconds later. Taking the most recent positions of Uranus and that of the star (C. Lecacheux, personal communication), this point is found to be 4".1 away from the centre of the planet at a position angle of 349°. Assuming a circular orbit and correcting for foreshortening due to orientation of the axis of the orbit (assumed to be same as that of the planet), we arrive at a value of 53,000 km for its radius, and an approximate period of 9 h 30 min. The apparent motion of this satellite's shadow with respect to the observer is

Fig. 1 Light curve obtained during occultation of SAO 158687 by Uranus.

estimated to be 2.74 km s^{-1} , yielding the length of the chord joining the immersion and emersion points as 24 km.

The size of the body can be estimated from the occultation light curve, where the dip is only 53% of the total star light. This can be explained by postulating that the stellar disk subtends an angle comparable to that of the satellite and the occultation in partial. We assume a typical stellar diameter of 3.5×10^{-4} arc s for a K5 star with the appropriate distance modulus³. Then, from a model of the occultation geometry, and taking into account the diffraction near uniform edges, we find that the estimated diameter will be around 70 km. The visual magnitude of the satellite is estimated to be ~ 19 .

We conclude that the body is a new satellite of Uranus.

Spectral variability in X-ray sources

COE *et al.*¹ have reported that Cyg X-1 and the transient source A 0620-00 both display anticorrelated spectral variability. That is to say, flux enhancements at low energy ($E \lesssim 10 \text{ keV}$) tend to be accompanied by a decline at high energy and vice versa. Both sources may be considered possible black holes; Cyg X-1 is well known, while the candidacy of A 0620-00 ($\equiv$ Nova Monocerotis 1975, distance $\gtrsim 2 \text{ kpc}$)^{2,3} follows if its peak luminosity $\gtrsim 5 \times 10^{38} \text{ erg s}^{-1}$ is identified with the Eddington limit luminosity $1.3 M/M_{\odot} \times 10^{38} \text{ erg s}^{-1}$ for mass accretion. Thus the accreting object has a mass $\gtrsim 4 M_{\odot}$, just greater than the accepted limiting mass for a neutron star. It has therefore been suggested¹ that anticorrelated spectral variability, perhaps resulting from inverse Compton scattering in the accretion

disk^{4,5} may be common to X-ray emitting binary systems which contain black holes. In this paper, we wish to show that anticorrelated variability is not confined to sources which are black hole candidates.

We have examined published spectral data for the above two objects and four other well-observed sources — namely, Cen X-3, Her X-1, Cyg X-3 and Cir X-1. The references to all data used in this paper (more than 50 observations) are too numerous to mention here and are tabulated elsewhere⁶. In order to facilitate comparisons we have selected only those results for which a power law spectrum has been fitted, of the form

$$I(E) = AE^{-\alpha} \text{ (keV cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}) \quad (1)$$

In some cases the power law may not have provided the only fit to data but we assume that the quoted spectral index α characterised the spectral shape at the time of observation and allows ready comparison to spectra at other times.

Fig. 1 Spectral variability plots for black hole candidates A 0620-00 (2–15 keV) and Cyg X-1. Open circles: low energy, $\lesssim 30 \text{ keV}$; full circles: high energy, $\gtrsim 30 \text{ keV}$. The lines of best fit are shown.

Spectra displaying anticorrelated variability about a 'pivot' energy E_p are described by $I(E) = A'(E/E_p)^{-\alpha}$ where $A' = \text{constant}$. Comparison with (1) therefore implies that $A'E_p^\alpha = A$, or $\log A = C + S\alpha$, where $S (= \log E_p)$ and C are constant for the source in question. Therefore, in order to better quantify anticorrelated variability we have plotted spectral observations as points on the $(\alpha, \log A)$ plane (hereafter called spectral variability plots, or SVPs), looking for a linear correlation, Fig. 1 shows these data for Cyg X-1 and A 0620-00 and the clearly linear correlations confirm the findings of Coe *et al.*¹. Linear correlation coefficients and the associated negligible probabilities that these correlations could be due to random fluctuations are shown in Table 1. In particular, it is found that $S \sim 1.3$ and 0.9 implying $E_p \sim 20$ and 8 keV for Cyg X-1 and A 0620-00, respectively.

Application of this technique to the other sources (Fig. 2) leads to the surprising result that all four behave in a similar

Table 1 Summary of results

Source	<i>N</i>	$S \pm 2\sigma$	<i>R</i>	<i>P</i>
Cyg X-1	25	1.3 ± 0.2	0.92	< 0.001
A0620-00	8	0.9 ± 0.1	0.99	< 0.001
Cyg X-3	5	1.1 ± 0.3	0.97	0.005
Her X-1	9	1.3 ± 0.3	0.95	< 0.001
Cen X-3	5	0.9 ± 0.5	0.90	0.03
Cir X-1	10	1.3 ± 0.3	0.97	< 0.001

N is the number of observations; *R* is the correlation coefficient; *P* is the probability that the correlation arises by chance.

manner to the black hole candidates. Taken alone the result for Cen X-3 is only marginally significant; nevertheless it produces a value for *S* similar to that for the other sources (see Table 1). In all cases best fit values of *S* lie between 0.9 and 1.3 corresponding to E_p values between 8 and 20 keV. It would appear therefore that all six sources display anticorrelated spectral variability.

We have discriminated between observations made predominantly below and above 30 keV ('low' and 'high' energy) in order to determine if spectral breaks unrelated to time variability have introduced spurious effects. We have sufficient data for Cyg X-1 to allow formal fits to be made with and without the low energy points. No significant difference in the

quality of the fits or in *S* values could be obtained. Low and high energy data points are distinguished for all the sources in Figs. 1 and 2 and we conclude that there is no evidence to suggest that the correlation between *S* and α is caused by energy dependence of the spectral exponent.

This study suggests that anticorrelated spectral variability may occur in X-ray sources other than those favoured as black hole candidates. It will be of interest to see if proposed inverse Compton emission mechanisms which show promise of explaining the observations for the black hole candidates^{4,6} can be generalised for binary systems involving say, neutron stars or white dwarfs.

We thank W. R. Webber, K. B. Fenton and A. G. Fenton for discussion, and the Australian Research Grants Committee for support.

Statistical mechanics of microemulsions

At low surfactant concentrations, an oil-water microemulsion may be represented as two immiscible continuum fluids, oil and water, dispersed in one another so as to form two interpenetrating, multiply connected regions, with the surfactant adsorbed at the interface between them. Scriven¹ has pointed out that as the oil/water ratio is increased, three types of structure will evolve in succession: starting from the oil-in-water emulsion to be expected at low oil content, there should be a smooth transition to a bicontinuous structure, in which neither phase can be said to surround the other, followed by a second transition to a water-in-oil emulsion when the oil content is sufficiently high. It seems likely, as Scriven suggests, that the phase diagrams reported for microemulsion systems involve all of these structures. Here we propose a statistical mechanical model for microemulsions, based on a simple procedure for generating random two-fluid geometries. Over certain ranges of the model parameters, the resulting free energy-composition surface shows regions where a bicontinuous phase may coexist with an oil-in-water and a water-in-oil emulsion; such three-phase equilibria have been observed experimentally². Our calculations also suggest a possible explanation of the very low interfacial tensions sometimes found between microemulsion phases.

To determine, at least within a constant of proportionality, the number of configurations available to the oil and water regions in a microemulsion of specified composition, we restrict ourselves to the class of geometries resulting from a two-step process, consisting of a Voronoi tessellation³⁻⁵ followed by random segregation into oil and water domains. *N* points are first distributed completely at random over the volume *V* to be occupied by the microemulsion; with each of these Poisson points, we associate the polyhedral region which lies closer to it than to any of the other (*N* - 1) points (Fig. 1). In the second step, *N*_o of these polyhedra are selected at random to be occupied by oil, and the remainder filled with water; the result is a random two-fluid geometry in which the oil occupies a fraction $v_o = N_o/N$ of the total volume.

Fig. 1 *a*, Two dimensional representation of the partition process. Shaded regions are occupied by oil, unshaded regions by water; heavy lines indicate the surfactant monolayer. *b*, Typical Voronoi polyhedron.

The number of distinct positions available to a Poisson point is proportional to the volume V , the proportionality constant $1/\omega$ being one of the model parameters. It is the size of ω that determines the scale of the microemulsion structure, and it is through ω that information about the molecular nature of the water and oil fluids enters into the model. The number of configurations for the placement of all N points is then

$$(V/\omega)^N/N!$$

and for each configuration there are

$$N!/N_0!(N-N_0)!$$

ways of assigning the oil and water labels. The configurational entropy of the microemulsion is therefore

$$S = -Vkc(\ln(\omega c/e) + v_0 \ln v_0 + (1-v_0) \ln(1-v_0)), \quad (1)$$

where $c \equiv N/V$ is the concentration of Poisson points.

To translate equation (1) into predictions about the thermodynamic behaviour of the system, we need an expression for the surfactant concentration σ in terms of c and v_0 . We assume that all of the surfactant is located in a monolayer at the interface between the oil and water regions, and that there are no oil-water contacts unmediated by such a monolayer. The surfactant concentration thus fixes the oil-water interfacial area.

The total area per unit volume of the surface generated by the Voronoi tessellation³ is $2.91c^{1/3}$, and the total length of the polyhedral edges in unit volume is $5.83c^{2/3}$. Only a fraction $2v_0(1-v_0)$ of the total surface will actually separate oil from water polyhedra; furthermore, since each edge is shared by three polyhedra, the probability that it lies on the oil/water interface is $3v_0(1-v_0)$.

We assume that a plane interface between the oil and water regions adsorbs α moles of surfactant per unit area, but that a curved surface will, because of crowding of surfactant segments, have a somewhat lower surfactant capacity. This curvature effect is introduced into the model by lowering the amount of adsorbed surfactant by β moles per unit edge length. The expression for σ derived from these considerations is

$$\sigma = (5.82\alpha c^{1/3} - 17.5\beta c^{2/3})v_0(1-v_0) \quad (2)$$

Equations (1) and (2) together may be used to determine the configurational free energy $G = -TS$ as a function of σ and v_0 (in calculating c for a given value of σ , we use the lower of the two roots of equation (2)). If the results are expressed in reduced quantities

$$G^* = \omega G / e V k T, \quad \sigma^* = \omega^{2/3} \sigma / 17.5 e^{2/3} \beta \\ \alpha^* = \omega^{1/3} \alpha / 3.0 \beta e^{1/3}$$

the reduced free energy G^* will depend only on σ^* , v_0 , and α^* ; the shape of the free energy surface, and therefore the phase equilibria to be expected, are entirely determined by the dimensionless parameter α^* .

Figure 2*a* shows plots of G^* against v_0 for various values of σ^* at $\alpha^* = 2.0$; below $\sigma^* = 0.247$, the plots show two symmetrically placed minima, the locations of which represent the compositions of two microemulsion phases in equilibrium. In Fig. 2*b* we have plotted (schematically only, in order to show the region of negative curvature) the minimum values of G^* from Fig. 2*a* against σ^* . The two compositions at which the double tangent touches the curve correspond to a bicontinuous phase ($\sigma^* = 0.247$, $v_0 = 0.5$) in equilibrium simultaneously with two other microemulsions of lower surfactant content ($\sigma^* = 0.102$, $v_0 = 0.121$, and $\sigma^* = 0.102$, $v_0 = 0.879$)—in other words, a three-phase equilibrium.

Figure 3 shows the three- and four-phase domains in the three-component phase diagram for various α^* : a mixture whose overall composition is located in the interior of a triangle or quadrilateral separates into phases with compositions given by the vertices; for α^* values outside the range 1.63–3.5 only two-phase equilibria are possible. The apparent violation of the phase rule by the four-phase regions found below $\alpha^* = 1.75$ results from the symmetry between the oil and water components imposed by our model. The slightest perturbation of this

Fig. 2 *a*, Reduced free energy plotted against volume fraction of oil at $\alpha^* = 2$ and several values of σ^* . *b*, Schematic plot of minimum free energy against σ^* .

symmetry leads to replacement of the top and one side of a four-phase quadrilateral by the corresponding diagonal; the resulting triangle represents a three-phase equilibrium.

In addition to predicting, at least qualitatively, the existence of the multiple phase equilibria observed experimentally, our model also suggests the origin of the very low interfacial tensions between the separated microemulsion phases observed for certain systems². In Fig. 2b the maximum difference δ between the G^* curve and the double tangent is 0.0008, to be compared with a difference $\delta' = 0.47$ between the reduced free energies for the corresponding homogeneous and phase-separated mixtures in Fig. 2a. Although no quantitative calculations have yet been made, the implication is strong that a very thin layer of the bicontinuous phase can reduce the interfacial tension between a water-in-oil and an oil-in-water microemulsion by several orders of magnitude.

Fig. 3 The three- and four-phase regions at various values of α^* .

Our aim has been to offer a minimal model of microemulsion phase equilibria, a model which leads to a purely entropic free energy function. In the absence of composition-dependent energy contributions, all phase equilibria should be independent of temperature, in apparent contradiction to experimental fact. It should be remembered, however, that the model assumes an ideal surfactant, one which exists only at the water/oil interface. The balance between hydrophilic and lipophilic interactions required for such optimal performance will in general be quite sensitive to temperature changes, particularly in the case of the surfactant-cosurfactant systems used in practice.

Toxic fluorinated compounds as by-products of certain BF_3 -catalysed industrial processes

WE have embarked on a programme of toxicity tests on a range of industrial chemicals that are manufactured using boron trifluoride (BF_3) as a catalyst. Although this study is still in its early stages, we feel it opportune to draw attention to the fact that in some of the samples we have detected low concentrations of fluorinated compounds, some of which merit serious toxicological concern. The most notable example we have uncovered concerns some industrial chemicals that are manufactured from ethylene oxide using BF_3 as catalyst. On the basis of the results of toxicological studies of these products, we suspected fluoroacetate precursors as contaminants, and subsequent chemical analysis has confirmed the presence of low concentrations of 2-fluoroethanol and/or 2-(2-fluoroethoxy) ethanol. These two compounds are known to be very toxic to mice (LD_{50} 10 and 15 mg kg^{-1} respectively) and are regarded as fluoroacetate precursors^{1,2}. The latter is the addition product of 2-fluoroethanol and ethylene oxide (equation 1), and 2-fluoroethanol is the formal addition product of fluoride ion to ethylene oxide (equation 2).

This explanation of the genesis of the two fluoroacetate precursors points, not to BF_3 itself, but to fluoride ion as the source of the toxicants. That F^- is a common by-product of BF_3 -catalysed reactions is further supported by the identification of tetrafluoroborate ion (BF_4^-) as a contaminant of some of the other samples we have examined. For this chemical is the readily-formed product of interaction between F^- and BF_3 . The origin of fluoride ion is unclear; it might derive by solvolysis of BF_3 —or of silicon tetrafluoride, SiF_4 , a known contaminant of commercial BF_3 .

Fuller details of these studies will be published elsewhere.

Aragonite in Permian Reefs

PRESERVATION of aragonite in fossils decreases the further we go back in the geologic record. In the Palaeozoic, aragonitic remains have been found only in clayey-bituminous deposits which have largely inhibited diagenetic alterations of unstable mineral phases (for example, Buckhorn Asphalt and Kendrick Shale, both Upper Carboniferous of USA¹, and Upper Oil Shale Group, Lower Carboniferous of Scotland²). Palaeontological information preserved in these facies is restricted, however, to those organic remains which lived in the equivalent basinal environments or were transported into them. Original mineralogy and microstructures of ancient reef organisms can generally only be deduced from analogies with equivalent younger counterparts. The oldest known reef-organisms with preserved aragonitic microstructures were

Table 1 Microstructure, cement and aragonite contents in typical Permian reef organisms of Djebel Tebaga (southern Tunisia)

found in the Upper Triassic (Lower Carnian) of the Southern Alps³. Here, early burial of patch reefs and reef detritus by clayey-tuffaceous sediments and porosity diminution of the carbonates by subsequent cementation have probably inhibited transformation of aragonitic microstructures into calcite⁴. In this report we describe investigations of microstructures and diagenesis in calcareous sponges which have revealed aragonitic primary structures and cements in material from the Upper Permian of Djebel Tebaga, Southern Tunisia.

The Upper Permian specimens were collected from small patch reefs and their marginal reef detritus, intercalated in an irregular sequence of sandstones and marls, crinoidal, brachiopod and fusulinid limestones⁵. Calci-sponges (Inozoa, Sphinctozoa) and sclerosponges are the main reef-builders. They are associated, especially in the marginal reef areas, with stromatolites and solenoporaean algae. The enigmatic tabulate coral-like fossil *Permosoma permotessellata* (Parona) is, in places, a successful frame-builder. Rugose corals, so close to their presumed extinction

on the Permian-Triassic boundary, have been found only in two places and do not contribute to reef construction. The marginal areas of the patch reefs and the surrounding reef detritus have yielded the greatest number of individuals and species. Externally the specimens are rather well preserved, beautifully washed out by recent erosion, but appear highly altered by diagenesis. Calcareous sponges are often partly or totally dolomitized.

Fig. 1 *Disjectopora* sp., Upper Permian, Djebel Tebaga (Tunisia). T 7/1. Vertical thin section through astrorhizal canal with two tabulae, showing spherulitic aragonite cement along the outer margin and blocky calcite in the centre of the voids. Primary microstructure of the skeleton obliterated by recrystallisation. Bar represents 100 μ m.

Fig. 2 Chaetetid sclerosponge, Upper Permian, Djebel Tebaga (Tunisia). T 209. Spherulitic microstructure of the skeleton, partly recrystallised. Bar represents 10 μ m.

The occurrence and distribution of aragonite was first shown by staining thin sections with Feigl solution. Thirty specimens, mostly calcareous sponges (pharetronids, sclerosponges), a few corals, calcareous algae (solenoporaean) and *Permosoma* were X-rayed for determination of calcite, aragonite and dolomite concentrations. In 20 samples aragonite contents were between 1% and 37%; 10 samples were free of aragonite, and in three samples dolomite contents were up to 36%. Aragonite is patchily distributed in the massive skeletons of the above groups and/or as a thin veneer on the skeletal elements. This veneer is the first generation of cement, with acicular shaped crystals which were often translucent (Fig. 1). The preservation of organic microstructures does not necessarily improve with an increase in aragonite content. As can be seen from Table 1, even with complete recrystallisation of the original crystal fabric, the remaining aragonite content may reach 20%. As has already been stated for Triassic calcareous sponges³, the occurrence of certain microstructures is not a consistent generic feature of calcareous sponges. Representatives of *Stellispongia*, for instance, which exhibit

clinogonal or irregular arrangements of aragonite crystals in the Triassic, have spherulitic microstructures in Permian species: the latter fabric is the most common in Permian calcareous sponges, having been encountered in inozoans⁶, sphinctozoans⁷, sclerosponges (Fig. 2) and stromatoporoids (disjectopores). Clinogonal microstructure has been found in one specimen of *Stellispongia*, and the tube-walls of *Permosoma permotessellata* (Parona). Tabulae and opercula of this species show irregularly spherulitic structure⁶.

The surprising preservation of aragonitic organic microstructures and cements in the Permian reef deposits of Tunisia is being subjected to further mineralogical and geochemical investigations. Material so far examined demonstrates that even 'hopeless' facies with obviously complete diagenetic alteration may still retain a large amount of mineralogical and microstructural information.

Field work was carried out with M. Scherer. I thank W. Kühne for providing samples.

The Grenville Province as a shear zone

PALAEOMAGNETIC and structural data on the Grenville Province in North America are best explained if the Grenvillian 'orogeny' was caused by right-lateral simple shear of the entire Province. Relative displacement of the edges of the belt is estimated at 200–300 km.

Apparent polar wander paths (APW) for the Grenville Province are clearly distinct from the North American path at the corresponding time (Fig. 1). This abnormal distribution has been explained by a collision between the Province and the rest of the continent^{1–3} or by an extra loop of the North American APW path⁴. Relative ages of magnetisation from minerals that have given two distinct polar positions would all seem to indicate however that the collision model is palaeomagnetically more satisfactory. Geological evidence, on the other hand, militates against the existence of a suture anywhere in the Grenville Province. The model thus requires that the postulated suture be hidden under the Appalachians, and that the Grenville Province be an ancient analogue of the modern Tibetan plateau^{1,5}.

Another hypothesis that satisfies palaeomagnetic constraints is that the Grenville 'track' formed by counter-clockwise rotation of individual structural elements inside the Grenville Province. Samples that show two directions of magnetisation separated by very large angular distances come from severely deformed areas, whereas individual poles closest to the normal position for North American poles at that time come either from rocks close to the Grenville Front or from highly resistant, moderately deformed zones. By contrast, poles from samples collected in strongly deformed belts, or far from the Grenville Front plot farther away along the Grenville track (Fig. 1). The length of this track suggests that samples from intensely deformed rocks may have suffered up to 60° of counter-clockwise rotation relative to other North American poles.

This interpretation of palaeomagnetic data makes it worth re-examining the structure of the Grenville Province. A

Fig. 1 Stereographic projection of palaeomagnetic pole positions from the Grenville Province. Michael gabbro (1); Grenville Front anorthosite (2); Shabogamo gabbro (3); Unfraville gabbro (4); Lac St Jean anorthosite (5); St Urbain anorthosite (6); post-Grenville Frontenac dikes (7); Wilberforce pyroxenite (8); Ottawa diorites (9); Magnetawan gneisses (10); Lac Allard anorthosite (11); M₁ and M₂, two pole positions from the Morin anorthosite. The apparent polar wander path for North America between 1150 and 950 Myr BP is sketched in.

northeasterly trending shear zone closely follows the Grenville Front⁶ and another, less developed, parallel belt marks the southeastern margin of the Province (Fig. 2). Between these two shear zones, the Province is broken into a number of blocks separated by north-northeasterly trending shear belts—'straight belts'⁷ such as the Chibougamau–Gatineau lineament⁸—that, in numerous cases, are underlined by mylonites. This pattern, visible in Fig. 2, is also present at larger scales.

Although strain measurements in the field show predominant flattening and/or constriction, deformation in straight belts must occur at least in part by simple shear at the scale of the belt. Rigid blocks of small dimensions are represented by granitic plutons and anorthositic massifs, whereas larger ones seem to correspond to fragments of an older basement that have escaped the brunt of Grenvillian deformation. Shear belts tend to follow strips of metasediments (marble and paragneiss of the Grenville Group) but also appear to have remobilised the basement where its pre-existing structures were suitably oriented. Where the map pattern indicates relative displacements along the edges of blocks, they correspond to counter-clockwise rotation of the blocks. Their rotation is thus antithetic to that of the Grenville belt as a whole. The structural pattern is thus everywhere compatible with deformation of the Grenville Province by overall simple shear (Fig. 2).

According to geochronological data, the Grenvillian event did not start much before 1150 My ago and was over by about 950 My ago. During this interval, the entire region was heated sufficiently for all K–Ar clocks to be reset. Rb–Sr isochron dates have also been reset in the Chibougamau–Gatineau shear belt, but this was not the case in the more rigid block located to the west of it.

By analogy with Labrador, anorthositic suites are commonly thought to be about 1400 Myr to 1500 Myr old, but Rb–Sr and U–Pb dates on the Adirondacks⁹, Morin¹⁰ and Lac St Jean complexes¹¹ are Grenvillian. Low ⁸⁷Sr/⁸⁶Sr initial ratios and apparent syntectonic emplacement of the

Fig. 2 Sketch of the Grenville Province and suggested shearing mechanism. Thicker continuous lines indicate boundaries of subprovinces; thin dashed lines show structural trends. Anorthosite massifs with mafic roots are dotted in, those without mafic roots are black. C, Chibougamau on the Grenville Front, at the north end of the Chibougamau-Gatineau lineament.

Morin pluton¹² indicate that those three anorthositic complexes are coeval with the Grenvillian deformation. In fact, the peculiar shape of the Morin massif may result from clockwise rotation of this pluton during its emplacement. The lack of a mafic root in all three massifs, by contrast with those of eastern Labrador, probably reflects syntectonic emplacement.

Numerous field studies have demonstrated the synchronicity of deformation and metamorphism in the Grenville Province, so that some heat source must have been available during deformation. Without this excess heat, it is indeed doubtful that such a wide zone (~300 km) would have been deformed by simple shear. The 1500 Myr old anorthositic suite occurs along a small circle that is in close geographical proximity to the Grenville Province. It is possible that the same deep-seated hot belt responsible for these plutons may have underlain the Grenville Province around 1,100 Myr to 1,000 Myr ago. As the Province follows a small circle of about 60° radius, one may envisage its deformation to have corresponded to clockwise rotation relative to North America around an Eulerian pole located at the centre of the circle. In more general terms, this style of deformation appears to be characteristic of Proterozoic mobile belts including the Pan-African ones¹³⁻¹⁵.

From apparent displacement of possibly equivalent rocks, the sum of right-lateral strike-slip motion across the Province is about 200-300 km, a figure comparable to those derived from apparent rotation of palaeomagnetic poles.

In this interpretation, the Grenville Front can be at various points a fault, a thrust or a metamorphic boundary, depending upon the location and the orientation of its

various segments relative to the overall shear direction. The synchronous opening of the Keweenaw graben is taken to represent a fracturing of the old brittle Archean craton, caused by right-lateral shear in the Grenville Province, whereas the intrusion of the Mackenzie diabase dyke swarm represents the tension phase that preceded and accompanied deformation in the Province¹⁶.

Implications of a revised fit between Australia and Antarctica for the evolution of the Eastern Indian Ocean

GRIFFITHS¹ suggested that the computer fits of Australia and Antarctica²⁻⁴ are not supported by geology and that a better fit can be obtained by moving Australia 250 km westwards along the coast of Antarctica in the computer fitted reconstructions. Griffiths's revised fit eliminates the overlap of the South Tasman Rise, now known to be of continental origin⁵, and the Iselin plateau. Laird *et al.*⁶ showed that new geological evidence from Tasmania and East Antarctica favour such a revised reconstruction over the older computer fits. We present a slight modification to the fits given by Griffiths and by Laird *et al.* that, in addition, allows a good fit of magnetic anomaly lineations and fracture zone trends on the India⁷ and Antarctic⁸ plates (Fig. 1). This revised reconstruction thus implies that India and Australia have been parts of the same plate since the time of anomaly 22 (about 50 Myr ago). It also substantially reduces the size of the postulated Greater India⁹⁻¹¹ (Fig. 2).

Figure 1 shows this reconstruction of the eastern Indian Ocean at anomaly 22 time. Australia is rotated to Antarctica by 30.9° about a pole at 11.9°N, 30.8°E. India is attached to Australia and rotated with it in Fig. 1. Magnetic lineations and fracture zones^{7,8,12} are also shown, with anomalies 23 to 28 shaded. The fit was done by eye, using the geological data⁶ as a constraint and the 2,000-m isobaths as the continental edges. There is some overlap in West Australia (also present in the computer fits²⁻⁴), and a gap in the Australian Bight, but the fit in the eastern sector is good.

As in the computer reconstruction of McKenzie and Sclater⁴, there is a large overlap of Kerguelen Plateau and Broken Ridge. Calcareous sediments of Cretaceous age have been recovered from both these features^{13,14} which indicates that they were elevated structures before Australia and Antarctica separated. Broken Ridge is an elongate tilt-block structure¹⁵ with a steep southern slope dropping into the Diamantina fracture zone. Kerguelen Plateau has been poorly mapped, but in outline it does seem to divide along approximately 55°S into northern and southern sections.

Fig. 1 Reconstruction of eastern Indian Ocean at anomaly 22 time. Antarctica fixed. Isobaths are 2,000 m for Australia and Antarctica (dashed), 3,000 m for Kerguelen Plateau (dashed), Broken Ridge and Ninetyeast Ridge north of inferred position of anomaly 22 (ref. 7). DSDP site 255 on Broken Ridge¹³ and the site of Eltanin core 54-7 (ref. 14) are shown. NP, Naturaliste Plateau. Equal area projection, 10° grid spacing.

Kerguelen and Heard Islands on the northern section have been the site of recent volcanism¹⁶ although early Tertiary limestones occur on Heard Island¹⁷. Cenomanian chalk was cored from the flanks of the deeper southern section¹⁴. We suggest, therefore, that the northern section of Kerguelen Plateau has been formed since the Eocene, and that the southern part is a remnant of an older structure, possibly

a ridge that consisted of Broken Ridge, the southern section of Kerguelen Plateau and Naturaliste Plateau.

India moved rapidly northwards away from Antarctica from the late Cretaceous until approximately the time of anomaly 22 when the rate and direction changed markedly^{4,7,8}. At approximately this same time, Australia broke away from Antarctica¹⁸. The reasonably good match

Fig. 2 East Gondwanaland with India in the computer fit² with a computer fit⁴ of Australia as a dashed line.

of the fracture zones and magnetic anomalies on the India and Antarctica plates in Fig. 1 implies that at the time of anomaly 22, India and Australia became joined together as parts of the same plate and motion on the Ninetyeast transform fault ceased.

Sclater and Fisher⁷ in their model for the evolution of the eastern Indian Ocean used a computer fit⁴ between Australia and Antarctica for their reconstructions. This left a longer distance between the sequences of anomalies 22–32 on the India and Antarctica plates than in Fig. 1. As India and Australia are now on the same plate, Sclater and Fisher were forced to maintain a three-plate configuration between the times of anomalies 22 and 11 with right lateral strike-slip motion on the Ninetyeast transform fault. Thus the reconstruction in Fig. 1 suggests that this complexity is unnecessary.

Because the west coast of Australia seems not to have been open to the sea until the Jurassic¹⁹, several authors have suggested that the original Indian continental fragment extended to the west coast of Australia^{9–11}. The revised Australia–Antarctica fit brings Australia approximately 250 km closer to the reconstructed position of India and reduces the extent of 'Greater India' by this amount (Fig. 2). In this new reconstruction, the width of the portion of 'Greater India' between the locus of the present Himalayan Front and the margin of Western Australia is about 600–700 km. As the Himalaya are about 300 km wide and crustal shortening of about this much is suggested by geological and geophysical observations^{20–22}, we contend that essentially all of this Greater India could be absorbed in the Himalaya without the need for postulating the subduction of a large continental fragment beneath Tibet^{9–11}.

Thus the revised reconstruction of Griffiths¹ and Laird *et al.*⁶ not only improves the geologic fit between Australia and Antarctica but allows for a simpler model for the evolution of the east Indian Ocean⁷ and for a smaller amount of material to be absorbed in the Himalaya than had been supposed^{9–11}.

Sensitivity of the homing pigeon to an Earth-strength magnetic field

THROUGH the use of a flight tunnel constructed within a controlled magnetic environment, it has been possible to train three pairs of homing pigeons (*Columba livia*) to discriminate between the presence and absence of a 0.5 gauss (Earth-strength) magnetic field. Successful discrimination was associated with flutter activity of the birds within the tunnel.

The ability of homing pigeons to return from an unfamiliar release site may depend upon a system of 'map and compass' navigation^{1–3}. Celestial sources of compass information have been demonstrated with pigeons^{4,5} and migratory birds^{6,7}. Sources of map information, however, have remained obscure^{2,3,8}. The occurrence of homing under a wide variety of experimental and natural conditions suggests that several environmental cues are involved.

Characteristics of the Earth's magnetic field, if detected, could participate in the formation of a complete navigational grid. Both the total field strength and the vertical field component (angle of inclination) are maximum at the poles and minimum at the magnetic equator. The angle of declination (between the geographic north and magnetic north meridians) shows complementary variation with longitude.

Early field tests of magnetic orientation were conducted by comparing the homing performance of birds with attached bar magnets to birds with attached non-magnetic equivalent weights⁹. Conflicting results were obtained under sunny test conditions, and no conclusions could be drawn.

Through experiments in which the birds' internal biological clocks were reset, it was found that the Sun provided only compass information^{4,5,10}. Thus, a new series of magnet experiments was prompted by the demonstration of Keeton¹¹ that pigeons could orient and home from an unfamiliar location under complete overcast by using Sun-independent cues. The vanishing bearings of experienced birds released with magnets under overcast were found to be randomised¹². In sunny conditions, however, only experienced birds released at greater distances or first-flight youngsters were disoriented. With a pair of battery-powered Helmholtz coils, Walcott⁴ was able to induce more uniform vertical magnetic fields through the pigeons' heads. By reversing the battery polarity, it was possible to change the inclination of the resultant field and obtain predictable and reversible orientation responses¹³. Normal fluctuations of less than 70 nT (1 gamma = 10⁻⁹ T) in the Earth's magnetic field have also been shown to correlate with the orientation performance under Sun of both pigeons¹⁴ and Singbilled gulls¹⁵. In pigeons, attached magnets have been used to suppress the correlation¹⁶. Walcott (private communication) has found the bearings under Sun of birds released near natural magnetic anomalies to be randomised. Together, these observations suggest that the Earth's magnetic field has a role in the normal navigation of homing pigeons.

With specially designed cages, it has been possible to record the orientation preferences of migratory birds in response to various environmental cues. W. and R. Wilt-schko^{17,18} and Emlen *et al.*¹⁹ have obtained predictable and biologically appropriate responses from several species of birds to natural and artificial magnetic stimuli. Attempts thus far to record the meaningful orientation of pigeons within cages have been unsuccessful, however, and other behavioural techniques have been applied. Using classical conditioning of the pigeon's heart rate, Kreithen and Keeton have demonstrated a sensitivity to polarised light²⁰ and to small changes in barometric pressure²¹. Reille²² reported some positive results in response to magnetic

stimuli; however, Kreithen and Keeton²³, Beaugrand²⁴, and Bookman (unpublished observations) have been unable to repeat or extend his findings. Attempts by several investigators to use operant conditioning with magnetic stimuli have also been unsuccessful²⁵ but largely unpublished. Previous laboratory testing has therefore failed to provide a conclusive demonstration of magnetic sensitivity in the homing pigeon, leaving the suggestive results of outdoor test releases unconfirmed.

Earlier laboratory experiments, particularly those using classical conditioning, required that the pigeons be restrained from active movement. The design and construction of a flight tunnel (Fig. 1) permitted greater activity, including voluntary flight, during the testing period.

Training was undertaken to determine if pigeons could learn to discriminate between a 0.5 G induced field and the 0.02 G background field. During a preliminary period of adaptation to the testing apparatus, it was found that mated pairs of birds were much more active within the tunnel than single birds. Therefore, intensive training was undertaken with three mated pairs borrowed from several lofts.

After 2 weeks, the birds' behaviour had been sufficiently shaped to allow the recording of data. Each trial began by uniformly releasing a pair of birds at the tunnel entrance. The pigeons then travelled the length of the tunnel and were trained to enter the correct feeding box associated with each magnetic field condition. The sequence of magnet coil activation was determined at random and set before the start of each trial. To serve as a positive reinforcement, food was available only from the correct feeding box. Incorrect responses were punished by confining the bird within the box for 30 s before allowing it to enter the correct box. All trials ended with the recovery of both birds from the correct box. Only the first response of the first bird was recorded, as the second bird did not respond independently. For the duration of testing, the birds were housed in cages within a naturally-lighted and ventilated room, and maintained within 10% of their *ad lib.* weight.

Two basic patterns of response were observed during adaptation and training of the pigeons. After landing, the birds would either walk the length of the tunnel or engage in a period of spontaneous 'flutter' activity before entering a feeding box. Flutter consisted of sustained hovering, jumping, rapid turning and short flights. Trials with at least 3 s of continuous flutter activity were recorded as 'with flutter', the remainder were designated 'no flutter'. A summary of the data is presented in Table 1. The cumulative performance record for one pair of birds is detailed in Fig. 2.

The data indicate that a statistically significant discrimination had occurred. This was even more apparent when the trials were separated according to flutter activity.

Fig. 1 Pigeon flight tunnel. Top view (a) and side view (b) of flight tunnel as constructed within mu-metal shielded room. Shielding reduced the natural magnetic field to a level of 0.02 ± 0.01 G. Three pairs of Helmholtz coils (H) were connected in series and arranged to induce a vertical magnetic field (B) along the length of the tunnel in as uniform a manner as possible. Each coil was wound with 150 turns of 12 gauge copper wire. Approximately 7.5 V d.c. at 100 mA was required to induce a 0.5 G (Earth-strength) magnetic field, as measured from a central probe (G). When the coils were not in use, the current was diverted across an external equivalent resistance. Two feeding boxes with concealed food bins (F) were located at the far end of the tunnel. For each trial, food in one bin was accessible while food in the opposite bin was covered by an aluminium screen that prevented access. Birds could be confined within the boxes by remote-controlled doors (D) which were released by string (S). Illumination was provided by 12 V d.c. lamps (L). A closed-circuit television camera (C) and electrical patchboard (E) allowed monitoring and control to proceed from a separate room which housed the power supplies, gaussmeter and television monitor. Scales: upper, 1 ft; lower, 1 m.

Table 1 Summary of flight tunnel training results

Pigeons		No. of trials	No. correct	Percentage correct	Probability*
Cornell pair	Total	150	101	67.3	< 0.0001
	With flutter	89	68	76.4	< 0.0001
	No flutter	61	33	54.1	NS
Richards pair	Total	129	89	69.0	< 0.0001
	With flutter	61	50	82.0	< 0.0001
	No flutter	68	39	57.4	NS
Walcott pair	Total	36	23	63.9	< 0.15
	With flutter	16	13	81.2	< 0.025
	No flutter	20	10	50.0	NS

*Two-tailed binomial probability for observed distribution.
NS, Non-significant (random) distribution.

In all cases, the 'with flutter' trials were statistically non-random while the 'no flutter' trials were random. Performance of the birds was not below the chance level in any category. The only factor altered from one trial to the next was the applied magnetic field. Although attempts were made to prevent any inadvertent cues (such as power supply hum), the influence of any such cues on discrimination would probably be independent of flutter activity. Therefore, the finding of significant differences between trials with and without flutter suggests that inadvertent cues or experimenter-induced bias did not influence the results.

Fig. 2 Richards birds: cumulative record. Graphs for one pair of birds showing the number of trials with correct responses against the total number of trials. Only the response of the first bird to make a response was recorded for each trial. Lines indicating the 50% (chance) and 100% (perfect; upper line) levels of performance have been added. *a*, The total trial sequence is shown. Note that a significant discrimination had occurred and that 'no flutter' (○) and 'with flutter' (×) trials were distributed throughout the testing period ($P < 0.0001$). *b*, 'With flutter' (×) trials graphed separately ($P < 0.0001$). *c*, 'No flutter' (○) trials graphed separately (non-significant). Significant discrimination only occurred in the 'with flutter' trial sequence.

Thus, it seems that homing pigeons have a magnetic field sensitivity that can be demonstrated in the appropriate laboratory setting. Unlike other more conventional senses, the magnetic sense is somehow associated with flutter activity. Fluttering is also seen in successful experiments with caged migratory birds¹⁷⁻¹⁹. Although fluttering may be directly involved with the mechanisms of perception, it is just as likely to reflect a more general sensory activation that accompanies orientation. The biological mechanism of magnetic sensitivity in birds remains unknown, but may include paramagnetic, inductive or ferromagnetic interactions. The testing of pairs of birds in a flight tunnel is a straight-forward laboratory technique that could be applied to these and other unanswered questions in orientation research.

This study was supported by the Sloan Foundation and the Massachusetts Institute of Technology. I thank Dr W. Richards for advice and Dr W. T. Keeton, Dr C. Walcott and L. Richards for supplying pigeons. This paper is

dedicated to the memory of Dr Hans-Lukas Teuber, who provided the original inspiration.

Autogeny in saltmarsh mosquitoes induced by a substance from the male accessory gland

OVARIAN maturation by mosquitoes and other haematophagous Diptera without a prior blood meal is called autogeny, while the term anaautogeny applies to those cases where blood is necessary. Many populations of the saltmarsh mosquito, *Aedes taeniorhynchus*, contain both autogenous and anaautogenous females¹⁻². Moreover, within this species there are two types of autogenous females: (1) those that need a stimulus from mating to produce eggs autogenously and (2) those that lack this requirement³. We report that autogenous egg production associated with mating is triggered by a substance from the male accessory gland. The stimulation of normal oviposition behaviour and the termination of sexual receptivity in the female mosquito are also caused by a male accessory gland substance which is introduced into the female during mating^{4,5}. Both of these responses are uniformly exhibited by all females of several species⁶.

To demonstrate the influence of the accessory gland on ovarian maturation, we injected non-blood-fed, virgin females with tissue and fluid obtained from sonicated male accessory glands. This suspension was prepared by placing the glands of 250 virgin males in 1 ml of saline solution⁷. Since each female was injected with 1 μ l of suspension, our standard dose was equivalent to one-fourth of a pair of male glands. Males were at least 5 d old before paired accessory glands were removed. We used two closely related species, *A. taeniorhynchus* and *A. sollicitans*, both as the recipients and the sources of glands. All experiments with *A. taeniorhynchus* involved either the Rutgers stock or the Lake Charles strains. There are no laboratory colonies of *A. sollicitans*. Thus, we used F₁ offspring of wild adults collected in Indian River County, Florida. Procedures for rearing and maintaining mosquitoes followed those of O'Meara and Evans⁸.

Only a few non-injected and saline injected females developed eggs (Table 1), but over half of the *A. taeniorhynchus* injected with male accessory gland fluid (MAGF)

produced eggs in the absence of a blood meal. The ovarian stimulant associated with the gland seemed to be non-specific since *A. taeniorhynchus* responded in a similar fashion to material from either *A. sollicitans* or *A. taeniorhynchus*. The observed frequencies of autogeny in both the Rutgers stock and the Lake Charles females injected with accessory gland material were equivalent to the levels obtained in our previous studies where the females were allowed to mate³. During all treatments the vast majority of the *A. sollicitans* females remained anautogenous (Table 1). Of the 1,005 *A. sollicitans* females examined only four were autogenous. The rare occurrence of autogeny in *A. sollicitans* evidently is independent of MAGF and probably any other factor associated with mating.

The ovarian maturation associated with MAGF injections was not an artifact caused by just a general increase in the total protein concentration of the mosquito's haemolymph. Neither human serum nor protein from the fat bodies of male *A. taeniorhynchus* stimulated autogenous egg development (Table 1). For the various treatments, the amount of protein injected into each female was as follows: 10% human serum, 10.0 µg; 5% human serum, 5.0 µg; MAGF (*A. taeniorhynchus*), 0.25 µg; male fat bodies, 0.25 µg. The amount of protein that the females obtained from MAGF was quite small. Thus, most of the protein for autogenous egg production must have come from the female's internal reserves which were accumulated during the larval stage.

The ability of male accessory glands to induce ovarian development is acquired sometime after adult emergence. Females show no ovarian response when they are injected with MAGF from very young males (<1 h old).

At least three hormones are involved in the overall regulation of ovarian development in mosquitoes^{9,10}. Both autogenous and anautogenous females seem to use the same general endocrine pathway. Differences have been discovered in the mechanism controlling release of egg development neurosecretory hormone (EDNH) (ref. 11), however. Some *A. taeniorhynchus* females need no external stimulus

to trigger the release of EDNH and thus they begin autogenous ovarian maturation even before they are mated. Blood feeding will also trigger the release of EDNH and, possibly, MAGF does the same.

The association of MAGF with autogeny might represent another matrone-induced phenomenon. Matrone, a male accessory gland substance, is responsible for stimulating normal ovipositional behaviour and for terminating sexual receptivity in the female^{12,13}. These responses to matrone, however, are normally exhibited by all females in a mosquito population, whereas only a portion of the *A. taeniorhynchus* females in a population respond to the male accessory gland factor by producing eggs.

In *A. taeniorhynchus*, geographical variation in autogenous fecundity seems to be controlled by polygenic factors¹. Results of preliminary crossing and selection experiments indicate that other genetic factors control the occurrence of the various types of autogenous and anautogenous females. Attempts to identify the major genetic components involved in the regulation of autogeny are in progress.

The occurrence of two types of autogenous females within a mosquito population has been observed in other species besides *A. taeniorhynchus*. Working with the arctic species, *Aedes impiger* and *Aedes nigripes*, Corbet¹⁴ found both obligate and facultative autogeny. Females with the facultative type of development were potentially anautogenous for several days after emergence. But, if they did not succeed in obtaining a blood meal, then they switched to an autogenous mode of egg maturation. Corbet¹⁴ postulated that this change in the female's reproductive strategy was a response to the female's energy reserves, although no experimental study has produced evidence to support this theory.

Clearly, male-induced ovarian maturation represents a facultative form of autogeny and the switch from potentially anautogenous to autogenous development is mediated by a chemical from the male accessory gland. Most *A. taeniorhynchus* females are refractory to insemination for at least 36 h after emergence^{15,16}. The average duration of this refractory period is about 72 h in both the Lake Charles and Rutgers stock strains. Where insemination is a prerequisite for autogeny, the refractory period would contribute to the delay in the onset of ovarian maturation. As long as the ovaries remain undeveloped the females continue to be active blood-feeders and the fecundity in the initial egg batch is greatly enhanced in those mosquitoes that feed at this stage. Such a flexible system involving autogeny enables the females to capitalise on the availability of suitable hosts while at the same time it provides a means whereby egg maturation can occur in the absence of any host. Additional studies are needed to determine if mating and MAGF influence ovarian maturation in other mosquito species.

MAGF-AS	274	0.4	15
Saline	293	0.7	10
Non-injected	230	0.4	31

Sexes were separated within 3 h after adult emergence. All tests were conducted with virgins who had access to 10% sugar solutions. Females were denied oviposition sites and they were considered autogenous only when at least one ovarian follicle had completed maturation to stage V. Males were at least 5 d old before their accessory glands were removed. If mated the autogeny rates were about 50% in both the Rutgers stock and the Lake Charles strains (see ref. 3).

*Females injected with 1 µl of solution 2–3 days after emergence and then examined for ovarian development 7 days later.

†Mean no. of eggs per autogenous female.

Influence of the seminal plug on mating behaviour in the garter snake

PHEROMONES are used by a wide variety of animals to identify the social status, sex and reproductive state of conspecifics¹. In snakes, olfactory cues are involved in prey selection and trail following^{2–4}, recent experiments indicate that female sexual attractivity in the garter snake *Thamnophis sirtalis* is oestrogen-dependent and that sexually active males discriminate between, and preferentially court, oestrogen-injected females^{5,6}. We report here that in the closely related species, *T. radix*, sexually active males do not court recently mated females. This discrimination is based on the presence of a seminal plug normally deposited by the mating male during copulation, and the mating plug exerts an inhibitory effect on the courtship activity of other males.

Courtship and copulation in *Thamnophis* are readily identifiable behaviours. Male approach is visually guided^{7,8} and courtship behaviour is mediated by tongue-flick delivery of odour molecules to the vomeronasal organs as in trail-following^{2,3,7,9}. The male orients to and approaches the female, tongue flicking rapidly^{5–7}. At first contact, the male frequently drapes his tongue over the female's back, the probable source of the sex attractant⁷. If the female is sexually attractive, the male will begin to 'chin rub', a behaviour in which the male places his chin on the female's back and repeatedly traverses her length. The male then aligns his body beside the female's with his head resting behind the female's. Palpations with the posterior third of the body follow as the male slides back to oppose the cloacae. Female sexual receptivity is characterised by lifting the tail and gaping the cloacae¹⁰, stimulating the male to evert and intromit a single hemipenis. Snake hemipenes are complex structures with numerous calyces and spines, believed to have a role in the copulatory lock¹¹. Copulation in the laboratory has an average duration of 91 min (range: 28.22–188.73 min) and is very vigorous. Sperm transfer is followed by the deposition of a gelatinous material produced by the renal sex segment, forming a copulatory plug^{8,12,13}; it has been suggested that the plug functions to reduce sperm leakage and prevent insemination by other males (ref. 13, but see ref. 14). Following separation, the male is sexually refractory for at least 24 h.

To assess the effect of mating on female sexual attractivity, attractive females were retested for sexual attractivity after having been allowed to mate. Female attractivity decreased markedly after mating and the decline was immediate and long-lasting (Table 1). Most non-mated males failed to court mated females even though they had courted the same female immediately prior to the female's copulation.

To determine the role of the mating plug in the post-mating decline in female attractivity, the mating plug was expressed and the female's cloaca laved with 10 ml distilled water immediately following mating. Females were then retested for attractivity (see Table 1 for protocol). Females with mating plugs removed remained attractive to sexually active males: seven of eight females were courted during the retest.

As in lizards and various other vertebrates and invertebrates (reviewed in ref. 15) mating in *Thamnophis* seems to inhibit further female sexual receptivity. In lizards, this decline in receptivity following mating is immediate and a consequence of male intromission¹⁵. In the present experiment, recently mated females which had had the mating plug removed were courted vigorously but failed to raise

the tail and gape the cloaca in response to male palpation for at least 48 h after mating; thus, they were attractive but not receptive.

To establish further that the post-mating decline in female attractivity was related to the mating plug, a third experiment was conducted in which cloacal material from both recently mated females and from courted but unmated females was collected and applied to sexually attractive females. Results demonstrated clearly that the mating plug is responsible for the loss of female attractivity following mating (Table 2). Females rubbed with cloacal material from unmated females or distilled water were actively courted; however, most females with cloacal material from recently mated females were not courted. Most females were courted after the applied material was removed with a wash of alcohol followed by water.

As these experiments were in progress, it became apparent that the behaviour of sexually active males changed dramatically following exposure to a mated female. To assess the effect of exposure to a mated female on subsequent male courtship, recently mated females were introduced into cages containing proven sexually active males (as determined by consecutive male courtship of two injected but unmated females immediately before presentation of the mated female). After a 5-min test with a mated female, the unmated females were reintroduced in order and male courtship of each scored. Exposure to a mated female precipitated a marked reduction in male courtship activity; if exposed to a mated female, previously sexually active males (nine of eleven) did not court females they had just courted. The duration of this effect varied between males.

T. radix exhibit a reproductive cycle typical of high latitude species. In the spring, breeding is restricted and compressed into the first days after emergence from the winter hibernaculum^{12,16}. Males emerge several days before females¹⁷ but do not leave the area. On emergence, females are courted *en masse* by the males in the immediate vicinity; mating 'balls' of 100 or more males courting a single female have been reported. It is not known if this mass courtship facilitates female receptivity. It appears that once a single male intromits, the unsuccessful males abruptly leave the copulating pair^{7,12,18}, further, recently mated females are usually not courted¹².

Table 1 Influence of mating on female attractivity in the garter snake *Thamnophis radix**

Treatment	N	No. of females courted
Pre-mating	17	17
Post-mating:		
5–20 min	9	0
24 h	16	2†
36–48 h	11	3†

*Not all females were retested for attractivity at all intervals post-mating. All behavioural tests were 5 min in duration. Males were considered to be sexually active if they courted the female uninterrupted for 30 s; a female courted consecutively by two males was considered sexually attractive. Precautions were taken to avoid transferring odours through handling. Animals were purchased in September from a commercial supplier in Wisconsin. Snakes were handled 1–2 ml of a meat-egg-vitamin mixture each week. Water for drinking and soaking was available *ad libitum*. Male snakes were kept individually in wire mesh enclosures (61 × 22 × 77 cm). Unmated females were housed in groups of six in wire cages; mated females were separated and caged individually. Cages containing males and testing cages were inside Sherer Gillett RI-48-LLTP environmental chambers programmed to provide a 14:10 L:D photic cycle with a corresponding thermal regimen of 32:23 °C; females were exposed to a 14:10, 27 °C daily photothermal cycle. All snakes were intact and received the following hormone treatment. Males were induced to a sexually active state by subcutaneous (s.c.) implantation of a 2.0 cm silastic capsule (0.15 mm inside diameter) containing approximately 16 mg of free testosterone. Females received daily s.c. injections of oestradiol benzoate^{5,6} (50 µg per day); injections were discontinued on the eighth day. N, no. of animals tested.

†In two cases, post-mating courtship involved the same test male.

Table 2 Role of mating plug in mating-induced decline in female attractivity

Treatment	N	No. of females courted
Pre-test:		
Untreated	18	18
Test:		
Cloacal wash		
mated female	7	1*
unmated female	7	7
Distilled water	4	4
Post-test:		
Alcohol-water wash	18	15†

Females were tested for sexual attractivity using protocol described in Table 1. In the first of three consecutive courtship tests, the sexual attractivity of the females was established. Cloacal material from recently mated females or unmated females, or distilled water, was then applied to the dorsal surface and the females were retested for attractivity. Females were then washed with alcohol (90%) followed by distilled water to remove the applied substance before being retested for attractivity. N, no. of animals tested.

*Male courtship weak.

†Of the three non-courtied females, two were not courtied during the post-test period because of the decline in male courtship behaviour as a result of the exposure to mating plug material (see text).

These field observations of male dispersal from the mating pair suggest that the mating male deposits an odour(s) during copulation which communicates to other males the mated status, and hence non-receptivity, of the female. Thus, it is possible that the mating plug may, in addition to aiding in sperm retention, enable other sexually active males to determine whether a particular female has mated recently.

The experimental finding that exposure to odour(s) secreted during copulation (presumably by the male's urogenital system) results in sexually active males 'losing interest' in unmated, sexually attractive females, however, suggests an alternate explanation for male dispersal from the mating ball. In those insects having dense mating aggregations in which the probability of multiple inseminations is high (intense sperm competition), mechanisms have evolved which reduce the likelihood of multiple inseminations¹⁹. It is possible that, in *Thamnophis*, the odour(s) deposited by the mating male maximise the male's reproductive success by subsequently decreasing female attractivity as well as temporarily removing other males from the breeding population (that is, while the recently mated male is sexually refractory and unable to mate). Male dispersal from the mating ball, therefore, could be a consequence of unsuccessful males avoiding these odour(s). The demonstration and clarification of either or both of these postcopulatory adaptations must await detailed field studies of *Thamnophis* sexual behaviour.

Field observations also indicate that females leave the vicinity of the hibernaculum soon after emergence and copulation¹⁷. Since copulation is prolonged and conspicuous in *Thamnophis*, the mating pair is presumably very vulnerable to predation at this time. Mating-inhibition of further female sexual attractivity and receptivity, therefore, may act along with the female's departure from the hibernaculum area to minimise the female's vulnerability to predation (see also refs 15, 17).

Although our findings may be due to the restricted testing conditions, they demonstrate that sexually active males do not court sexually attractive females after prolonged or forced exposure to copulation odour(s). The specificity of this decline in male courtship behaviour as a consequence of exposure to a mated female is indicated by the observation that such males continue to investigate introduced snakes and trail-follow. It would thus be of interest to know whether this cessation of courting behaviour is due to a change in sensitivity at the peripheral or central level. In any case, the demonstration in verte-

brates that the mating plug of one male can influence the behaviour of other males toward other females is, to the best of our knowledge, unique.

Copulatory plugs, restricted mating opportunities and reproductive competition among male garter snakes

REPRODUCTIVE competition for females among males of a given species can take many forms, some of which (like mating plugs) may place constraints on the mating opportunities of males and intensify competition for available females. I have studied the reproductive behaviour of two garter snake species (*Thamnophis sirtalis* and *T. butleri*) in the field for 5 years. They do not exhibit pair-bonding, paternal care of offspring, territoriality, or intrasexual combat. Sexual selection in this mating system should favour males which compete to locate, court and mate with the maximum number of females¹. Yet I have observed numerous solitary female *Thamnophis* within the same time periods and areas in which other females were being vigorously courted, often by several males. I have previously observed that the anterior cloaca of any recently mated female *Thamnophis* contains a copulatory plug which occludes the oviductal orifices². The plug evidently is formed by the copulating male after sperm transfer. I interpreted this as a form of intrasexual competition in which the successfully copulating male makes the female temporarily unavailable to other males and reduces the likelihood of multiple inseminations. Some reports^{3,4} indicate that multiple inseminations are possible. I present here evidence from the field that male garter snakes recognise females with a copulatory plug and behave as if these females were unavailable.

The pattern of emergence from hibernation and mating has been described for *T. sirtalis* in Canada⁵⁻⁸, but my own observations differ in several important respects. Mating activity in southeastern Michigan is most intense on warm days in March and April immediately following the emergence of these snakes from hibernation, but before they disperse from the denning area. A denning area in Michigan is a collection of separate refuges, such as crayfish or rodent burrows, no one of which is used by all of the snakes at

that area. Males are conspicuous throughout the mating season, either courting or actively moving through the denning area evidently searching for females which might be emerging from any of the refuges. The emergence of females from hibernation is sporadic with individuals appearing on different dates. Females showing evidence (the copulatory plug) of recent mating do not immediately disperse from the denning area. These females, however, were never being courted when I encountered them. By contrast, those females which did not have a plug were usually being courted (Table 1).

The hypothesis that females with cloacal plugs are unattractive to males was tested in the field. Individual male snakes were given the opportunity to court first a female with a plug and then a female without a plug. The results (Table 2) clearly show that sexually active males can recognise and are disinclined to court females with plugs. All of these males subsequently courted the females without plugs.

Table 1 Observed mating status and courting activity of female garter snakes

	No. being courted	No. not being courted	χ^2
<i>T. sirtalis</i>			
without plug	21	6	27.2
with plug	0	19	
<i>T. butleri</i>			
without plug	14	3	9.9
with plug	0	4	

Values are the total number of females observed at the mating areas during the mating seasons from 1974 to 1976. Mating season is defined for each year as the time from the first observed courtship to the last.

A male can increase his opportunities for mating by minimising the time spent in unproductive courtship. It would be advantageous for a male to recognise and disregard females with plugs if plugs effectively prevent further inseminations. Among males in competition to locate unmated females, those that can recognise the altered mating status of a female as soon as possible should be favoured. Frequently, several males court a female simultaneously. When one mates, the unsuccessful males tend to disperse, presumably seeking other females, before their successful rival even finishes mating. I have seen this occur three times in the field and similar reports from the field⁹ and the laboratory^{10,11} exist. Even the successful male should soon be seeking other females. In at least four cases, males that I had observed mating were courting another female within

Table 2 Responses of male garter snakes to females with or without copulatory plugs

Species	N	Courted both	Courted neither	Courted only female with plug	Courted only female without plug	Probability
<i>T. sirtalis</i>	11	2	0	0	9	<0.01
<i>T. butleri</i>	13	0	0	0	13	<0.001

The mid-body portion of a female with a plug was carefully set in front of each male. Both the head and anal portions of the female were held by hand to prevent her retreat into the undergrowth. If the male contacted the female with his tongue and initiated normal courtship by aligning his body along the coils of the female's body with his chin pressed tightly against her dorsal skin, his response was scored as positive. A response was scored as negative only after a male contacted the female with his tongue several times and then ignored her. As soon as a score was obtained for a female with plug, she was removed and the procedure was repeated on the same male using a female without a plug. In this matched-pairs design, each male served as his own control. Probabilities are for a one-tailed sign test.

an hour. More extensive data on males mating more than once in one afternoon have been reported¹².

The mechanism by which male garter snakes recognise the altered mating status of females with plugs remains unknown. In my experimental field trials, the males did not seem to behave differently toward either female until tongue contact was made. The males made no attempt to investigate the female's cloacal area (which was within my hand) before courting or rejecting her. This suggests that a chemical cue which is not physically associated with the plug itself may be involved. I doubt that the cue could be from the plug itself inasmuch as that is a male product. If a male were capable of producing any substance which directly caused other males to disregard a female, it would be most advantageous to use it at the beginning of courtship to avoid competition from courting rivals, rather than reserving it for use (in plugs) after mating was completed. This is not observed. If this potential advantage ever existed for some males, competing males that disregarded male odours and courted anyway would be favoured. Alternatively, plugged females could find it advantageous to 'announce' their altered status, since courting aggregations may be just as conspicuous to potential predators as they are to human observers. If fruitful mating is unlikely, females should not risk predation. Therefore, the female is probably responsible for producing the cue.

Chameleons use accommodation cues to judge distance

Any animal that adjusts the focus of its eye lens has monocular distance information potentially available from its focusing mechanism. Such accommodation cues are independent of size and context, and thus could provide an objective measure of distance. Ingle has proposed that such information is used by monocular frogs¹ and toads², both of which he has shown to be capable of estimating distance with one eye³. There is no direct evidence, however, that any animal perceives distance as a function of the plane of focus of the image. The experiments described here demonstrate that chameleons do so in estimating the distance of their prey.

It has not been shown that chameleons judge distance when feeding; however, their method of catching insects seems to be sufficiently exacting to require accurate distance assessment: the tongue is shot out with remarkable speed ($\sim 5 \text{ ms}^{-1}$) to hit and retrieve insects at distances up to 1.5 times body length⁴ (Fig. 1). The eyes of a chameleon normally move independently, each eye scanning (saccadically) over more than a hemisphere. While taking aim at an insect, however, both eyes are swivelled directly towards the target (Fig. 2), often prompting the assumption that these animals acquire distance information by some process of triangulation.

Fig. 1 Multiple exposure photographs of a chameleon attempting to capture an insect. 35-mm black and white film (Kodak Tri-X) was loaded into an oscilloscope camera, and the shutter left open. Illumination was provided by a strobe light flashing at 2.5 ms intervals. The camera motor drive was triggered by hand as the chameleon took aim and the film then moved past the shutter at 16 inches s^{-1} , thus separating the frames. The chameleon is on the left and is viewed from the side; only his head is visible. The insect he is attempting to catch is on the right, mounted on the end of a wooden stick (hence the series of horizontal bars on the right). The scale is given by the marks on the stick (5-cm spacing). Time moves down the page. At the top the chameleon's tongue can be seen protruding from its mouth as it takes aim. Then the tongue can be seen shooting across the gap towards the insect. *a*, The chameleon is wearing lateral prism spectacles (see Figs 2 and 3) and the tongue passes freely by the insect, before being retracted. *b*, In contrast, when the animal is wearing negative lens spectacles (see Fig. 3), the tongue never reaches the insect. This undershoot is predicted from the hypothesis; but naturally occurring undershoots in healthy adult chameleons are extremely rare (less than 1 per 250 attempts).

Chameleons were filmed while attempting to catch insects at various distances. The species used was *Chameleo jacksoni*, which has horns from which opaque screens, lenses and prisms could be suspended such that the animal was required to look through them as it took aim (see Fig. 2). This made it possible to manipulate what the chameleon was seeing while it was taking aim.

If chameleons judge prey distance, then one might expect some quantitative aspect of their behaviour to correlate with the range of the insect (the object distance, D_{obj}). Occasionally, a chameleon will miss the target, and it is then possible to measure the maximum distance the tongue reaches (maximum tongue extension, S_{max}). This unobstructed tongue flight can be produced consistently by providing the animal with an illusory target (Fig. 3*a*). The results of a series of such binocular shots are shown

in Fig. 3*b*. There is a positive correlation between the behavioural measure (S_{max}) and the distance of the insect (D_{obj}). A similar series was filmed of animals feeding monocularly, and a similar correlation was found to exist (Fig. 3*c*). Thus chameleons do judge prey distance both monocularly and binocularly, as in both cases they modify their behaviour according to the target distance.

Chameleons have a focusing mechanism³, so in theory they could use accommodation cues to estimate distance monocularly (or binocularly). When the ciliary muscles of the eye are at rest, parallel rays of light are brought into focus on the retina⁴. As an object is brought towards the eye, however, at some critical distance the image will no longer be in focus, and the lens must subsequently be deformed continuously to maintain a clear retinal image as the object moves closer. Within this accommodating range, the degree of lens deformation, or the motor command used to effect that deformation, could give a measure of the distance of the object fixated.

It is possible to test whether chameleons use accommodation cues while feeding by altering the plane of focus of the prey. For instance, the image of an insect viewed through a biconcave (negative) lens lies closer to the animal than the insect itself. Thus if an animal estimates distance as some function of the plane of focus, it would undershoot in this situation. Conversely, it would overshoot if wearing biconvex (positive) lenses. For the animals for whom control data exist, it is possible to calculate quantitatively their predicted behaviour wearing spectacles with lenses of any strength. The curves drawn above and below the regression lines in Figs 3*b* and 3*c* show the expected deviations from normal behaviour for the particular focal length lenses used in the experiments. There is a close fit between the data obtained experimentally and the behaviour predicted under the hypothesis that chameleons estimate prey distance as a function of the plane of focus.

None of the other recognised cues to distance gives

Fig. 2 A chameleon wearing spectacles. Chameleon eyes normally move independently, each eye scanning (saccadically) over more than a hemisphere. When taking aim at an insect, however, both eyes are swivelled directly towards the target, and chameleons always aim and shoot their tongues straight ahead. Thus spectacles can be positioned so that the animal must look through them while taking aim.

predictions at all comparable with those from the accommodation theory. Indeed, of the monocular cues, motion parallax, retinal image size and context cues such as texture gradients and perspective, all change in such a way that the predicted behaviour for an animal wearing lenses would be qualitatively the opposite of that actually observed. Neither of the binocular cues, retinal image disparity or the convergence angle of the eyes, is in theory altered by the spectacle lenses, although it could be argued that in practice the animal will probably not be looking through the optical centres of the lenses, so there will be prismatic effects that may alter the convergence of the eyes. Chameleons, however, seem unaffected by alteration of the binocular convergence angle (Fig. 3b).

In conclusion, binocular and monocular chameleons

perceive prey distance as some function of the plane of focus, and accommodation is not just used as a back-up cue when binocular information is unavailable.

If an animal uses its focusing mechanism as its primary source of distance information, one might expect the structure of the eye to have design features maximising the accuracy of such a cue. To maximise the detection of error in focusing, the eye should have good angular resolution; the organisation of the chameleon eye suggests that these animals, particularly for their size, have high acuity vision. Chameleons⁵ have a well developed fovea, comparable in general appearance (deep convexiculate) with that of birds of prey^{3,7} renowned for their visual capabilities. Rochon-Duvigneaud's⁸ estimate of the chameleon foveal receptor cell density is probably much too high

Fig. 3 *a*, A chameleon viewed from above while shooting at an illusory target. The image of the insect is displaced laterally by thin prism spectacles, and the tongue in consequence passes by to the side of the real insect. The object distance (D_{obj}) is defined as the distance between the near side of the insect and the chameleon's pupils, measured on the film frame just before the tongue is fired. The maximum tongue extension (S_{max}) is defined as the distance between the pupils and the tongue tip, measured on the film frame where the tongue is maximally extended. *b*, *c*, The relationship between the range of the insect target and the maximum tongue extension for binocular (*b*) and monocular (*c*) animals wearing spectacles (shown in section on the figures). Each point represents one attempt by one of the three animals tested. ○, Attempts where animals wore just lateral prism spectacles; —, regression lines fitted to the data giving equations of the form

$$S_{max} = a(D_{obj}) + b \quad (1)$$

---, Overshoots and undershoots predicted by the hypothesis for animals wearing lens spectacles. The distance of the focal plane from the chameleon's pupil ($D_{focal\ plane}$) can be calculated from the lens equation, the distance between the eyes and the spectacles (see Fig. 3a) being taken into account:

$$D_{focal\ plane} = D_{specs} + 1/[1/F - 1/(D_{obj} - D_{specs})]$$

where F is the focal length of the lens. Predicted S_{max} can then be calculated for different insect ranges, by substituting $D_{focal\ plane}$ for D_{obj} in equation (1). Using the appropriate values for a and b , curves were calculated for negative lenses (focal length -25 cm) and positive lenses (focal length $+22.3\text{ cm}$). These are the curves shown. ●, ▲, Data points obtained from animals wearing these lenses as spectacles. The close fit between the data and the predictions suggests that both monocular and binocular animals estimate prey distance as a function of the focal plane. In contrast, note the crosses (+) on Fig. 3b. These points were obtained from binocular animals wearing convergent prisms of sufficient angular deviation to predict dramatic undershoots if the animals were estimating distance as a function of the convergence angle of the eyes. Chameleons do not seem to triangulate to estimate distance.

(760,000 mm⁻²), but his ordering of chameleon cone densities (the greatest of all lizards) as lying between that of man and birds of prey, may be correct. Notice also how large the chameleon's eyes are compared with the head (Fig. 2). Absolute increase in eye size improves resolution if the receptor density remains constant, because with increasing eye size, a given object will project a larger image on the retina.

To maximise the error in focus itself, the system should have poor depth of field, which can be achieved with a wide aperture. Chameleons are capable of some pupillary constriction, yet in spite of high ambient light levels and the proximity of the insect (both of which would induce pupillary constriction in other animals⁹), chameleons maintain pupil dilatation while aiming (f /number of ~ 5). It is possible to hypothesise why chameleons should have evolved high acuity vision, for reasons other than to maximise the usefulness of accommodation cues to distance; however, the combination of good image resolution and poor depth of field is less easy to explain in other terms.

Walls⁶ expressed surprise that although lens-accommodating mechanisms are widespread within the animal kingdom, focusing mechanisms seemed to have failed to evolve into depth-sensing organs. I suggest that chameleons have evolved just such a system, and that it is possible that we may have underestimated the usefulness of accommodation cues to other animals.

This work was carried out in the Zoology Department, Oxford University and the Massachusetts Institute of Technology, Cambridge, Massachusetts. I was supported in England by an SRC postgraduate grant and in the United States by a scholarship from the Kennedy Memorial Trust. My thanks to my supervisor Richard Dawkins, John Churcher, Tom Collett and David Ingle for their help and encouragement, to Jonathan Leakey for supplying me with animals and to Lawrence Young and Howard Hermann for hospitality at MIT.

Stereopsis in toads

HARKNESS'S demonstration¹ that chameleons rely primarily upon accommodative cues to judge distance encouraged me to examine the mechanisms of depth vision in an amphibian (*Bufo marinus*). Unlike chameleons which have highly mobile eyes, toads make neither convergent nor fixating eye movements, so that, except for stabilising reflexes, their eyes are almost locked in their sockets². For simple forms of stereoscopic range finding it is an advantage to have immobile eyes because disparity measurements can be converted directly into estimates of absolute depth (Fig. 1a). One might therefore expect toads to use retinal disparity in judging the distance of their prey. Toads have the essential apparatus for stereopsis: there is a substantial binocular overlap both in front of and above the animal³, the inter-

Fig. 1 a, Plot of the relation between disparity (a) and target distance (T) for a toad with an interpupillary distance of 3.2 cm. This value was typical of the toads tested. The relation between a and T depends on the lateral position of the target with respect to the toad's mid-line (β). However, this effect was negligible for the values of β that occurred in these experiments. b, Diagram to show how base-out and base-in prisms cause toads to misjudge the distance of a target. The dashed lines and open circles indicate the apparent lines of sight and positions of the target.

ocular distance is relatively large, and neural pathways bring information from corresponding areas on the two retinæ to the same region in both mid-brain⁴ and thalamic⁵ visual areas. My results suggest that toads do indeed make disparity measurements and should be added to the growing list of vertebrates known to achieve stereopsis (monkey⁶, cat⁷, owl⁸). In addition, toads have a mechanism for measuring depth within their extensive monocular field. Ingle has shown⁹ that frogs and toads, like chameleons, can estimate the distance of prey almost as well with one eye as with two, and the present data suggest that they do this by monitoring the accommodative state of their eyes when the prey is in optimum focus, as Ingle originally proposed¹⁰.

The accuracy with which toads assess the distance of their prey was determined from films of toads catching meal worms on the ground. Films were taken from above at 24 or 40 frames s⁻¹. When a toad snaps at prey within its frontal field it leans forward, extending its tongue. Two measures were derived from the films. 'Target-distance' (T) is the distance from a point midway between the eyes before the toad moves to the middle of the prey (or, when large dummy stimuli were used, a point 0.5 cm from its nearest edge). 'Snapping-distance' (S) is the distance from the same point between the eyes to the tip of the tongue at its fullest extent. Figure 2a shows that the tip of the tongue tends to overshoot the centre of the prey by about 1 cm. Thus a toad's snap includes an accurate estimate of target-distance.

The cues toads use to judge distance were studied by filming prey-capture at 40 frames s⁻¹ while toads wore lenses or prisms which distorted vision in their frontal field. Spectacle lenses alter the effective optical power of the eye so changing the normal relationship between the distance of an object and the lens position in which the image is in focus on the retina. Accordingly, a spectacle lens will systematically distort depth estimates that depend on the position of the lens. Negative spectacle lenses decrease the apparent distance of an object from u to $1/(1/u - 1/f)$, where f is the effective focal length of the spectacle lens at the principal point of the eye, and u the actual object distance. Prisms were used to assess the importance of stereopsis. Because amphibia have no fovea from which corresponding points in the two retinæ can be labelled, disparity is defined in a slightly unusual way, as the angle formed between lines connecting a target to the nodal point of

each eye (Fig. 1a). This is geometrically equivalent to the conventional meaning of disparity for conditions in which the lines of sight through the foveas are parallel. For a target that is straight ahead the relation between disparity and distance is given by the expression $\tan \alpha/2 = a/2T$, where T is the target distance and a the interpupillary distance. Prisms appropriately aligned change the apparent disparity of the target and thus alter the apparent target distance for an animal using stereopsis (Fig. 1b). Prisms that are base-out over each eye increase the apparent disparity (α') of the target by an amount equal to the summed angular deviation produced by the two prisms

Fig. 2 *a*, Accuracy of prey capture in binocular and monocular toads snapping at meal worms moving on a dark substrate. Snapping distance is plotted against target distance. In this and subsequent graphs each data point represents a single snap. The toads tend to shoot about 1 cm beyond the centre of the target. ●, Data from seven binocular toads. ○, Monocular: data from a single toad which arrived from the animal dealer with one eye missing. *b*, The effect of -136 mm negative lenses on snapping distance. ●, Monocular: lens placed in front of one eye while the other eye is occluded. The line labelled *M* is the predicted snapping distance on the assumption that toads employ accommodative cues. △, Binocular lenses over both eyes. Line *B* is the predicted snapping distance (taking into account the prismatic effect of the lens), assuming that toads depend upon stereopsis and ignore monocular cues. When vision is monocular the toad appears to use accommodative cues, but when vision is binocular disparity measurements are more important. Data from one toad snapping at a yellow cylinder moved by hand in its frontal visual field.

at the eyes (2δ); that is $\alpha' = \alpha + 2\delta$. Base-in prisms have the opposite effect ($\alpha' = \alpha - 2\delta$). Thus, given the normal relation between S and T (Fig. 2a), the snapping distance can be predicted for a variety of lens and prism combinations. The fact that this technique can be applied successfully implies that snapping is an open-loop response in the sense that the toad decides how far it is going to extend its tongue before beginning the movement.

The importance of accommodation as a cue to distance is demonstrated by the effect of a negative lens ($f = 136$ mm) on the snapping behaviour of a toad with one eye occluded (Fig. 2b). The toad then snaps short at prey in its frontal field. The data points fall around the line labelled *M* which predicts S on the assumption that distance measurements rely solely upon accommodative cues. If motion parallax or image size were significant cues to depth for monocular toads, negative lenses would cause overshooting. Some additional evidence also indicates that these cues are not important: (1) snapping accuracy is unaffected by prey size, and (2) when a target suddenly appears in front of a monocular toad, the toad usually snaps directly at it, without making any previous head movements. (One unexplained finding is that monocular positive lenses do not cause overshooting.)

Toads have a visual field of almost 360° within which they can detect prey. If the prey is close enough, toads snap at it directly without any prior orienting movement. Thus the toad's use of accommodative cues is not limited to a restricted region of retina. It must be less sensitive than that of the chameleon which always directs its fovea at prey before shooting out its tongue, so maximising its ability to detect and minimise blur.

The performance of toads wearing negative lenses over both eyes implies that disparity is the major cue to depth when targets are viewed binocularly. The snapping data then fall around the line labelled *B* (Fig. 2b) which is the predicted snapping distance on the assumption that disparity is the only measure of target distance. Tests with prisms reinforce this conclusion. Base-out prisms over both eyes cause the toad to undershoot by an amount which is greater the larger the angular deviation of the prisms (Fig. 3a), while base-in prisms cause overshooting. Prisms which are base-in over one eye and base-out over the other do not change the disparity of the target and accordingly have no effect on snapping distance. Instead the toad misses its prey laterally. Similarly, a base-out prism over one eye and an occluder over the other leads to lateral errors but no undershooting.

Base-out prisms produce a conflict between accommodative and stereoscopic information. Snapping distance is then a compromise between these two cues, heavily weighted in favour of stereopsis. Figure 3a shows that toads shoot beyond the point predicted by the apparent disparity of the prey by an amount that increases with prism strength (that is, with the magnitude of the discrepancy between the two cues). The relative importance of monocular and binocular cues was computed from snapping data taken from binocular toads wearing base-out prisms or combinations of base-out prisms and -136 mm negative lenses (Fig. 3b). For a wide range of prism strengths the data are well fitted by the linear expression

$$S = 0.94B + 0.06M + C$$

where C is a constant of about 1 cm. The expression holds for values of M between at least 8 and 30 cm and for values of B ranging from 5 to 15 cm. Thus, when vision is binocular, disparity is the predominant depth cue and accommodative cues are very largely ignored. Nevertheless, when vision is restricted to one eye, accommodation gives adequate distance information for targets in exactly the same part of the visual field (Fig. 2a).

If stereopsis is to operate over these distances without

Fig. 3 *a*, Plot of snapping distance against target distance for toads wearing base-out prisms over both eyes. The undershooting caused by the prisms increases with their strength. ●, Minimum angular deviation caused by each prism is 2.5°. ○, Minimum angular deviation is 9°. ▲, Minimum angular deviation is 15°. The solid lines show the predicted snapping distance on the assumption that toads employ stereopsis alone. In these predictions the distance (about 1 cm) between the prism and the eye is taken into account. Data from four toads snapping at a yellow cylinder moved by hand in their frontal visual field. *b*, Relation between *S* and a prediction of *S* derived from the expression $0.94B + 0.06M + 1.1$, with *M* and *B* defined as in Fig. 2*b*. This expression indicates that when targets are viewed binocularly disparity provides the major cue to distance, accommodative information playing a relatively minor role. The predicted value of *S* has been calculated for each data point (from plots like that of Fig. 3*a*) in which the target distance is 15 cm or greater. ●, Snapping responses of toads wearing one of five different prism strengths ($\delta = 2.5^\circ, 6^\circ, 9^\circ, 12^\circ, 15^\circ$). ○, Data points from toads wearing 136 mm lenses and one of three prism strengths (2.5°, 6°, 9°). The lines above the scattergram indicate the range of data points covered by each prism or lens-prism combination. Data from five toads. The goodness of fit of the data to this expression over the whole plot shows that the expression is an acceptable summary of the results.

convergent eye movements, a much greater range of disparities (about 35°) must be measured than is the case in human vision where a relatively narrow but exceedingly sensitive band of disparity detectors can be shifted to any desired position in depth. To confirm that eye movements are not essential for stereopsis in toads the effect of base-out prisms on snapping distance was examined in one toad with its medial and lateral extra-ocular muscles sectioned, and, as expected, base-out prisms continued to cause undershooting.

The experimental work was carried out in D. Ingle's laboratory at McLean Hospital, Belmont, Massachusetts. I thank him for his hospitality and for introducing me to his techniques. The work was supported by an Alexander Wernher Pigott Memorial Trust MRC travelling fellowship and by a grant from McLean Hospital. I thank L. Harkness, M. F. Land and P. J. B. Slater for reading the manuscript.

Functional test of tight junctions in the mouse blastocyst

THE mouse blastocyst contains a fluid-filled cavity, the blastocoele, which in normal Q-strain embryos first appears at about 83 h post coitum, when cleavage has produced a ball of about 30 cells¹. Two factors could be involved in the formation of the blastocoele: the secretion of fluid, which seems to be brought about by the coalescence and subsequent release of fluid-filled cytoplasmic vacuoles², and the development of tight intercellular junctions. Such junctions are first observed at the eight-cell stage, around the periphery of the embryo³; in the blastocyst they have increased in number and complexity to form the so-called 'zonula occludens', a permeability seal that can exclude lanthanum tracer from the blastocoele and thus presumably plays a role in maintaining the fluid turgor of the blastocyst⁴. By 'immunosurgical' dissection⁵ of Q embryos, we have investigated the stage of normal development at which the permeability seal becomes functional. We report here that impermeability to antiserum was not achieved until the mid-blastocyst stage (45–50 cells), and was not hastened or delayed by experimentally increasing or decreasing total cell number.

The technique of immunosurgery involves incubating embryos in the presence of anti-mouse antiserum; after thorough washing, the embryos are then incubated in complement. Cells coated with antiserum are briskly lysed; interior cells survive if and only if the antiserum has been denied access to them. As well as embryos grown *in vivo*, some aggregated and control cultured embryos were studied, to determine whether the total number of cells in the embryo affects the stage at which antiserum is first excluded. Table 1 shows that antiserum treatment lysed all cells in morulae and early blastocysts, up to 96 h after ovulation. At 97 h, 9% of *in vivo* blastocysts yielded some surviving cells; at 106 h, by which time the embryos were late blastocysts (containing over 100 cells on average), non-lysed cells were recovered from all.

Geometrical considerations suggest that a 17-cell embryo

*Estimates of cell number taken from Fig. 2, ref. 1.

†Numbers in parentheses represent the number of observations on which the mean is based.

Spontaneously ovulating females of the randomly bred Q- strain were used, kept in controlled lighting conditions with 16 h light, and 8 h dark centred on either 2400 or 1400. Ovulation and mating were assumed to have occurred at the midpoint of the dark period preceding the finding of the copulation plug. Embryos were either flushed from the uterus on day 4 or 5 of pregnancy (*in vivo*), and the zona pellucida removed with pronase, or recovered from the oviduct on day 3 of pregnancy and grown *in vitro* to a comparable stage of development. Cultures were carried out at 36 °C in a gas-phase of 5% CO₂ in air, under paraffin oil in 20 µl drops of medium 16 (ref. 14) after removal of the zona pellucida. Some of the zona-free eight-cell stages were aggregated into pairs or triplets before culture¹⁵. The method of antiserum treatment was similar to that used by Solter and Knowles⁵. Rabbit antiserum raised to mouse spleen cells was used at a dilution of 1/30 in phosphate-buffered medium¹⁴. Zona-free embryos were incubated in antiserum for 30 min at 36 °C, washed in phosphate-buffered medium at least four times, then incubated in 10% guinea pig complement (Wellcome, lyophilised) in isotonic saline for 30 min at 36 °C. Gentle pipetting dissipated the lysed and dead cells, so that any surviving interior cells could be clearly seen. These were counted after air-drying¹⁶ and staining with lactic-acetic orcein. Cell counts were carried out by the same method on some embryos before antiserum treatment.

should have at least one interior cell⁶. Direct observations have shown that cells may in fact become completely surrounded as early as the eight-cell stage⁷. If peripheral tight junctions formed a fully effective seal when they first appeared, at the eight-cell stage, immunosurgery should allow the isolation of even a single interior cell. It turns out that not only do no morulae survive antiserum treatment, but that the smallest number of cells that can be isolated in this way is about 15 (Table 1). Fifteen interior cells correspond to a blastocyst comprising *in toto* 45–50 cells^{8–10}. By this stage, the blastocyst *in vitro* is known to undergo a series of relatively rapid contractions of its cavity, followed by slower expansions¹¹. The blastocoele fluid seems to be restored and maintained by the action of the trophectoderm^{12–13}, desmosomes between trophectoderm cells are seen for the first time⁴, and the apparent turgor of the expanded blastocyst confirms that a permeability seal is operative. On the other hand in normal development the blastocoele first appears at about the 30-cell stage, before the tight junctions are fully capable of excluding antiserum. Unless the junctions form a one-way seal, impermeable to the passage of fluid from the inside outwards but not yet from the outside inwards, the existence of a fluid-filled cavity at this stage must depend on factors other than a permeability barrier. For example, the cavity could be maintained by a continuous release of fluid from the cytoplasm, or merely by a change in shape of the peripheral cells.

The results for aggregated embryos and their cultured controls are also shown in Table 1. Development *in vitro* was delayed by 7–10 h. Surviving cells were absent at 97 h, and were first observed 105 h after ovulation, both in the single and in the aggregated double blastocysts. By 114 h, non-lysed cells were recovered from the great majority of cultured embryos. The rate at which the proportion of embryos with some cells surviving increased did not differ

significantly between the single and double group, although the number of cells that survived was greater by almost twofold in the doubles than in the singles, and by almost threefold in the triples. The smallest number of cells recovered after antiserum treatment was 15 for single embryos *in vitro* (the same as *in vivo*), 27 for double, and 48 for triple embryos.

Thus, the time at which peripheral tight junctions are capable of excluding antiserum from the interior of the embryo does not depend on the size of the total cell mass. The time of first appearance of the blastocoele was also found to be independent of cell number, and was associated neither with the number of cell divisions nor with the chronological time elapsed since fertilisation¹. For blastocoele formation, the developmental clock could involve the number of DNA or chromosome replications, or possibly changes in nucleo-cytoplasmic ratio. Once blastocoele formation has begun, it may be that fluid pressure from the interior of the embryo is instrumental in the transformation of the semi-permeable system of tight junctions into a true zonula occludens.

Splenic T-killer cells can be generated by allogeneic thymic cells in conjunction with assisting factor

CELL-MEDIATED lympholysis (CML) is known to be brought about by thymus-derived (T) killer cells that have acquired reactivity towards antigens borne on target cells. To generate such T killer cells, cooperation between two subsets of T cells within the effector population is required—namely, T helper and T pre-killer cells¹⁻³. Helper T cells are thought to recognise Ia antigens^{4,5} and/or unique H-2 antigens⁶, while T pre-killer cells are known to recognise H-2 antigens^{4,5}. Ia antigens are found on B cells as well as on a certain sub-population of T cells⁷, whereas H-2 antigens have been described on virtually all B and T cells⁷. Plate has shown that a soluble factor from alloantigen-activated T helper cells assisted T pre-killer cells to differentiate into killer cells⁸. In this instance, soluble helper factor was generated in separate cultures containing mixtures of allogeneic cells, which was then assayed in a CML system from which T helper cells had been serologically removed. Since most thymic cells are known to lack Ia antigens⁷, they are conceded to be poor stimulators in both CML and mixed lymphocyte reactions⁹⁻¹¹. Nevertheless, they possess H-2 antigens and we reasoned that they might still serve to stimulate the generation of killer cells provided an assisting factor was incorporated from an exogenous source. In this way, T killer cells might be generated without at all disturbing the effector cell population by serological deletions. The data presented here support the idea that thymocytes alone are incapable of activating T helper cells, but that in the presence of exogenously produced assisting factor they do trigger development of T killer cells. The data also indicate a simple way by which assisting factors may be studied and by which requirements for CML may be delineated.

To illustrate the simplicity by which killer cells may be generated using this method, C57BL/6 spleen cells (10^7) were co-cultured, for sensitisation purposes, with allogeneic stimulator cells (10^7 , CBA/H X-irradiated with 2,000 rad) derived from spleen and thymus. Supernatant fluids were added to certain of the cultures containing thymic cells as stimulators, to assist the generation of effector cells. These fluids were added to cultures at the outset of the sensitisation phase in concentrations that ranged from 40 to 50% of the total volume, as noted in the tables. These assisting supernatant fluids were produced by co-culturing 10^7 C57BL/6 spleen cells for 48 h in a 5% CO₂ environment with a similar number of CBA/H spleen cells that had been X-irradiated with 2,000 rad. Such cultures were centrifuged at 170g for 10 min and filtered (0.45 µm Millipore filter) to eliminate viable cells. A control supernatant fluid was produced by culturing 10^7 C57BL/6 spleen cells alone. To test for killer activity, the ⁵¹Cr release assay was performed in microtitre plates according to the method of Simpson³.

CBA/H splenic cells served quite well to stimulate C57 splenic cells to become killers, whereas CBA/H thymic cells did not (Table 1). However, if supernatant fluid from allogeneic mixtures of splenic cells was included in the medium during the sensitisation phase, thymocytes were capable of sensitising the C57 splenic cells to become killers. Killer cells produced were specific only for the sensitising cells (H-2^b) (see Table 1). Supernatant fluids taken from C57 splenic

Table 1 Allogeneic thymic cells serve as stimulators of killer cells provided they are assisted by humoral factor(s)

|| After 5 d in culture, viable cells were counted by the trypan blue exclusion method and used as effector cells. Target cells were CBA/H splenic cells that had undergone blastogenesis for 2 or 3 d in the presence of concanavalin A (Miles) and that had been labelled with ⁵¹Cr (3×10^7 blast cells incubated with 100 µCi of sodium chromate for 90 min.). ⁵¹Cr-labelled target cells (10^5) were mixed with 2×10^5 or 4×10^5 effector cells, centrifuged for 5 min at 45 g and incubated for 3 h at 37 °C. Thereafter, the plates were centrifuged for 10 min at 170 µg and 100 µl of supernatant fluid was removed and assayed for released label with a gamma counter. To control for specificity of lysis, C57 effector spleen cells were co-cultured separately with splenic and thymic cells of (C57BL/6 × CBA)F₁ mice. Some of the latter were in the presence of KAF. After 5 d, effector cells sensitised to splenic cells achieved lysis equal to 52.1% and 0.7% against CBA (H-2^a) and C57BL/6 (H-2^b) target cells, respectively. Those effectors sensitised to thymic cells alone gave 10.8 and -2.0%; those sensitised to thymic cells in the presence of KAF achieved lysis of 59.1 and 6.1% respectively. In addition, those effector cells sensitised with CBA spleen failed to significantly lyse DBA/2 targets (H-2^a) (8.9%) as did effector cells sensitised with CBA thymus cells in the presence of KAF (8.0%).

§No s.d. provided as these values are averages of two experiments.

cells cultured alone were not able to help in generating killer cells (Table 1). The inability of C57 spleen cells cultured alone to produce killer assisting factor (KAF) could not be attributable to a reduction in cell viability at the end of the culturing interval (data not shown). An additional control not shown in Table 1 consisted of using no stimulator cells but only assisting supernatant fluid in the sensitising phase. This condition produced no killer cells indicating that both stimulator cells and KAF are essential to the process and that cellular fragments or antigens present in the supernatant fluids were not responsible for generating killer cells.

†50% of total culture volume.

‡Maximum and spontaneous releases were 5,132 c.p.m. and 927 c.p.m. respectively.

§C57 splenic cells were separated into two fractions by passage through nylon wool columns. Other aliquots of C57 spleen cells (40×10^6) were treated with θ -specific anti-serum (Thy-1.2 as in text) plus complement (agarose absorbed guinea pig serum) or with Ig-specific anti-serum (Cappel Labs.) plus complement for 1 h at 37 °C. Some C57 spleen cells were incubated with normal mouse serum plus complement and normal goat serum plus complement as controls. Following these treatments, the remaining viable cells were mixed with X-rayed CBA/H spleen cells to make assisting supernatant fluids, as described in the text.

To determine that T cells were, indeed, the killer cells in this system and to learn whether KAF was acting on killer cell precursors, fractionated splenic T cells and B cells were used separately as the intended effector cells during the sensitisation phase. Fractionated splenic T and B cell populations were obtained using nylon wool columns according to the method of Julius *et al.*¹². Since the nylon wool adherent cell population is known to consist of a mixture of B and some few T cells, this fraction was further treated with anti-Thy 1.2 serum (AKR-anti-C3H at 1:10 final dilution) plus agarose-absorbed guinea pig serum. The results shown in Table 2, which represent one of two parallel experiments, substantiate the known fact that splenic T cells, when confronted with allogeneic spleen cells as stimulators, will kill allogeneic target cells to approximately the same degree as do whole spleen cells acting as effectors (67.0% compared with 61.4%). Furthermore, just as with whole spleen cell populations, splenic T cells did not become effector cells when co-cultured in the presence of allogeneic thymic cells alone (10.6% and 4.8%). Splenic T cells, however, just as whole spleen cells, developed killer T cells when provided the double stimuli of allogeneic thymic cells and KAF (57.6% and 71.8%). Splenic B cells were unable to generate effector cells either in the presence of allogeneic whole spleen cell stimulators (1%) or in the presence of thymic cells and KAF (1.8%). As control, whole spleen cells intended as effectors were exposed to normal mouse serum plus complement prior to sensitisation. That these cells showed a slight increase in their ability to lyse target cells may be attributable to experimental error although other possibilities exist.

Experiments were also conducted to identify the cell source of KAF. This was accomplished by nylon wool separation of whole spleen cell populations and by serologically eliminating sub-populations from spleen cells and using the remainder in conjunction with irradiated allogeneic spleen cells for supernatant fluid production.

When splenic cells were depleted of B cells either with nylon or by anti-Ig serum and complement, the remaining cells produced KAF (Table 3). On the other hand, deleting T cells from splenic populations with nylon wool or serologically, eliminated KAF production. Indeed, these data (lines 7 and 8, Table 3) also show that KAF does not originate from the X-irradiated stimulator cells. Thus, two separate lines of evidence identify the source of KAF as T cells. We do not, however, exclude the possibility that the factor might be produced by other cells under other conditions.

Thus, a new simplified method has been described by

which thymic cells in conjunction with exogenously produced assisting factors will generate killer T cells for CML. KAF has been shown to be produced by T cells that are stimulated by allogeneic spleen cells. KAF was found to act upon T cells during the sensitising phase. Thymic cells alone serving as stimulators in the sensitisation phase, did not generate T killer cells. Exogenous KAF is therefore required as an additional signal when thymic cells are used as stimulators of pre-killer T cells. Whether KAF can be produced by stimulating T helper cells with cells that are not allogeneic, or with mitogens (concanavalin A) is not known. The exact requirements for the generation of KAF in this system as well as its antigenic and strain specificities are currently being investigated.

Cytotoxic T cells kill influenza virus infected cells but do not distinguish between serologically distinct type A viruses

THE molecular basis of recognition and target cell killing by cytotoxic T cells is still unknown. Doherty and Zinkernagel showed that mouse cells infected with lymphocytic choriomeningitis virus can be lysed by immune cytotoxic T cells but only if both cell types share at least part of the major

histocompatibility (H-2) region (see ref. 1). H-2 compatibility is also required for cell killing in other viral systems²⁻⁴, and for cells carrying non-viral antigens⁵⁻⁷. Our aim is to analyse the virus specificity of cytotoxic T cells, and the nature of their antigen recognition units. This requires a virus system with a small number of well characterised protein components, amenable to biochemical and genetic manipulation, as well as cytotoxic cells that will lyse target cells in a short term assay to minimise nonspecific cytotoxicity. Influenza virus offers many advantages for this type of study. The virion contains only two well characterised surfaced antigens, haemagglutinin (H) and neuraminidase (N), that are also expressed on the surface of infected cells⁸⁻¹¹, and can be purified in quantity. Virus strains are available with serologically distinct surface proteins, and with different internal proteins^{12,13}. Here we describe the generation of potent cytotoxic cells that are specific for histocompatible influenza virus-infected cells, but exhibit extensive cross-reactivity between the different type A influenza virus strains.

Fig. 1 Cytotoxic T cell-killing of H-2 compatible target cells infected with type A/Jap/Bel influenza virus. ⁵¹Cr release assay was carried out in microtitre II plates⁶, using 2×10^4 lymphoblasts or 10^4 P815 cells and varying numbers of immune cells per well as described by Simpson *et al.*²². Incubation was for 3 h. % ⁵¹Cr release = (counts released by target cells/counts released by 2.5% Triton X-100) $\times$ 100. Induction of cytotoxic cells: spleen cells after removal of red cells by 0.184 M NH_4Cl , were cultured with 2×10^6 stimulator cells for 5 days at 37 °C in Sterilin vials in RPMI 1640 medium supplemented with 10% foetal calf serum (FCS), 5×10^{-5} M mercaptoethanol (ME), and antibiotics (4×10^6 spleen cells in 4 ml per vial). Stimulator cells were syngeneic macrophages infected with type A/Jap/Bel (10^7 peptone-induced peritoneal cells were incubated with 100 HA units type A/Jap/Bel in siliconised tubes for 90 min at 37 °C and washed). Infection of target cells: 10^7 P815 mastocytoma cells (H-2^d, DBA/2) in 1 ml RPMI 1640 were incubated with 100 μCi ⁵¹Cr and 100 HA units type A/Jap/Bel for 90 min at 37 °C, washed three times, and incubated at 10^6 cells per ml in RPMI 1640 + 10% FCS for another 4 h. Lymphoblasts were obtained by stimulating 10^7 spleen cells in 10 ml RPMI 1640 medium supplemented with 10% FCS, 5×10^{-5} M ME and antibiotics for 2 d with 10 μg *E. coli* lipopolysaccharide in 25 ml Falcon flasks. Large blast cells were purified on a BSA gradient²¹ and labelled and infected as above. *a*, BALB/c spleen cells, cultured with macrophages for 5 d and assayed on ⁵¹Cr-P815 target cells. (Δ), Normal (unprimed) spleen cells, stimulated with infected macrophages, assayed on infected target cells; spleen cells from intranasally primed mice cultured with infected macrophages ($\circ$), or cultured with uninfected macrophages ($\square$), assayed on infected target cells; ($\bullet$) as ($\circ$), but assayed on uninfected target cells. *b*, CBA/H spleen cells (from intranasally primed mice) were cultured with infected macrophages and assayed on ⁵¹Cr-CBA/H lymphoblasts. ($\circ$) infected target cells; ($\bullet$) uninfected target cells; (Δ) cytotoxic cells treated with AKR anti-Thy 1.2²³ + C', assayed on infected target cells; ($\square$) cytotoxic cells treated with normal AKR serum and C', assayed on infected target cells.

An *in vitro* system for the secondary induction of spleen cells from primed mice¹⁴⁻¹⁸ was used to generate cytotoxic T cells which lysed influenza virus-infected cells in a 3-h assay. Virus was grown in embryonated chicken eggs and allantoic fluid was used as inoculum. Mice (2-3 months old) were primed by infecting them intranasally on two consecutive days with 4 HA units (0.05 ml) of influenza virus strain A/Jap/Bel (WHO nomenclature¹⁹); 5-12 weeks later spleen cells were put into culture with infected syngeneic macrophages for the *in vitro* generation of cytotoxic cells. After 5 d of culture, the cells were assayed for their ability to lyse ⁵¹Cr-labelled target cells infected with different strains of influenza virus. Either histocompatible P815 mastocytoma cells (H-2^d, of DBA/2 origin) or syngeneic lymphoblasts activated by *Escherichia coli* lipopolysaccharide (LPS) served as target cells. The latter were purified from bovine serum albumin gradients²¹, since virus replication occurred in blast cells only. We tested a number of mouse strains, but report only results with cytotoxic cells from CBA/H (H-2^k) or BALB/c (H-2^d) mice.

Primed BALB/c spleen cells cultured for 5 d with infected syngeneic macrophages yielded cytotoxic cells which lysed P815 cells infected with type A/Jap/Bel, but not uninfected P815 cells (Fig. 1a). Similarly, primed CBA/H spleen cells killed infected lymphoblasts, but not uninfected cells (Fig. 1b). Over a number of experiments the spontaneous release of ⁵¹Cr from infected P815 tumour cells was lower (5-15%) than that from infected lymphoblasts (15-30%); and the latter cells showed lower specific maximum ⁵¹Cr release. Lymphoblasts, however, have the considerable advantage of permitting studies of humans and outbred animals. The *in vitro* generation of the virus-specific cytotoxic cells requires the priming of spleen donors and the presence of virus-infected macrophages (Fig. 1a). The virus-specific cytotoxic cells are thymus-derived cells, since treatment with AKR antiserum to Thy 1.2 and complement²³ abolished the cytotoxic activity of CBA/H cells, whereas normal AKR serum and complement had a negligible

Fig. 2 H-2 restriction of cytotoxic killing. Experimental details, as for Fig. 1. BALB/c and CBA/H cytotoxic cells (CT) were generated *in vitro* by incubating spleen cells from mice that were primed with type A/Jap/Bel with syngeneic macrophages infected with type A/Jap/Bel. Syngeneic or allogeneic ⁵¹Cr-labelled lymphoblasts (LBL) were used as target cells. *a*, BALB/c CT cells assayed on infected BALB/c LBL ($\circ$), or uninfected BALB/c LBL ($\bullet$); CBA/H cytotoxic cells assayed on infected BALB/c LBL ($\square$), or uninfected BALB/c LBL ($\blacksquare$). *b*, BALB/c CT cells assayed on infected CBA/H LBL ($\circ$), or uninfected CBA/H LBL ($\bullet$); CBA/H CT cells assayed on CBA/H infected LBL ($\square$), or CBA/H uninfected LBL ($\blacksquare$).

effect (Fig. 1b). Similar results were obtained when BALB/c cells were treated with anti-Thy 1.2 (not shown).

The killing of influenza virus cells showed H-2 restriction similar to that observed with other viral systems¹⁻⁴. BALB/c (H-2^d) cytotoxic cells killed infected syngeneic BALB/c lymphoblasts but not infected allogeneic CBA/H (H-2^k) lymphoblasts (Fig. 2). Conversely, CBA/H cytotoxic cells killed infected CBA/H but not BALB/c lymphoblasts. A low level of cytotoxic activity was observed by the BALB/c lymphoblasts against allogeneic CBA/H lymphoblasts, but this cytotoxicity was directed equally to uninfected as well as infected cells.

The specificity of recognition by the virus-specific cytotoxic T cells was assayed using H-2 compatible target cells that were infected either with heterologous strains of type A influenza virus A/Jap (H₂N₂), A/Bel (H₀N₁), A/X31 (H₃N₂) (ref. 20) or with a B strain of influenza virus (B/Hong Kong). The type A viruses share internal antigens with type A/Jap/Bel (H₂N₁) but contain either serologically distinct haemagglutinins (H₀ or H₃) and/or neuraminidases (N₂). Note that type A/X31 does not share any surface antigens with type A/Jap/Bel, and that types A/Jap and A/Bel share the haemagglutinin or neuraminidase respectively. The type B/Hong Kong differs from the type A strains in both internal and surface antigens. BALB/c cytotoxic cells sensitised against type A/Jap/Bel lysed P815 cells infected with type A/Jap/Bel, A/Jap, A/Bel and A/X31 with equal efficiency, but did not lyse cells infected with type B/Hong Kong (Fig. 3). Conversely, incubation of spleen cells from B/Hong Kong primed mice with B/Hong Kong infected macrophages generated cells cytotoxic for B/Hong Kong infected but not A/Jap/Bel infected P815 cells (data not shown). We obtained the same specificity results when infected CBA/H lymphoblast cells served as target cells, and when cells were infected with another type B virus (B/Lee).

Our results demonstrate that T cell-mediated cytotoxicity of cells infected with influenza virus shows H-2 restriction as previously described for other virus systems¹⁻⁴. Of special

interest is the finding that at least a major proportion of the cytotoxic T cells are unable to discriminate between different type A influenza virus strains, whereas humoral antibodies can readily distinguish the haemagglutinin and neuraminidase proteins of these type A viruses. The T cell killing is virus-specific, since cells infected with type B influenza virus are not recognised by the cytotoxic cells generated with type A virus. Our results in the secondary response differ from those of Cambridge *et al.*²⁴, who report that a primary cytotoxic response is specific for the viral haemagglutinin in an 18-h assay. During the preparation of this manuscript we learned the Doherty and collaborators have observed cross reaction between type A viruses similar to our findings²⁵.

There are several possible explanations for the apparent difference in T and B cell recognition. T cells may recognise one of the shared internal viral proteins, provided it is expressed at the surface of infected cells. Alternatively, if the surface proteins (haemagglutinin and/or neuraminidase) are involved in T cell-recognition, the T cells would need to recognise a shared region of these surface proteins which for some reason is not immunodominant for B cells. Viral proteins expressed at the surface of infected cells may have a different conformation from those expressed at the surface of virions, resulting in the exposure of a shared region. It is also possible that T cell-mediated cytotoxicity is a more sensitive method of detecting cross reactivity than humoral antibody assays. Further studies with purified viral proteins will enable us to differentiate between these possibilities. Whatever the molecular basis of our observations, the cross reactivity for type A influenza virus strains at the T cell level is of obvious importance in immunisation against and the immunopathology of viral infections.

***In vitro* induction of immunological memory against testicular autoantigens**

By culturing normal rodent lymphocytes together with foreign stimulator cells, lymphocytes are generated, which can destroy target cells bearing transplantation antigens identical with the ones on the stimulator cells¹⁻³. When these stimulated lymphocytes are cultured further in the absence of the primary cellular antigen, they will revert, morphologically, to small lymphocytes⁴⁻⁶. These primed 'secondary' (2°) lymphocytes⁷ are functionally oligoclonal memory cells which can be reactivated only by stimulator cells, which resemble, antigenically, the ones that caused the primary stimulation. We have studied the occurrence of a parallel phenomenon with self, rather than foreign, tissue and have established that normal rat lymph node cells can be auto-sensitised *in vitro* against dissociated testis cells from the same donor animal⁸. I report here that the self responsive activated lymphocytes can also be made to revert back to quiescent small secondary lymphocytes

Fig. 1 *In vitro* generation of auto-sensitized EAO secondary cells. For primary auto-sensitisation 30×10^6 normal rat lymph node lymphocytes and 3×10^6 trypsin dissociated testis cells were incubated in 6 ml medium (Eagle's medium + 15% heat inactivated horse serum). After 4-5 d, the stimulated cultures were fractionated on a discontinuous Ficoll density gradient. The gradient consisted of five layers with decreasing density varying from 1.10 to 1.06 g ml⁻¹, and a top layer of Ficoll-free Eagle's medium. Centrifugation was at 10,000 r.p.m. (Beckman head SW27) for 60 min at 4°C. The purified blast fractions, containing more than 95% lymphoblasts, were seeded together with allogeneic embryonic fibroblasts (2×10^6 lymphoblasts, 1×10^6 fibroblasts) in 10 ml culture medium into 100 mm Petri dishes. After 11-14 d, the reverted small 2° lymphocytes were collected and confronted with fresh stimulator cells in microtitre plates (2×10^5 2° lymphocytes plus 1×10^6 irradiated lymph node stimulator cells (2,000 rad), or 1×10^5 dissociated testis cells, respectively). For determination of ³H-thymidine uptake, ³H-thymidine was added 24 h after starting the 2° cultures, and cells were collected in a multiple harvester after overnight incubation.

and that immunological memory can be induced *in vitro* against autoantigens.

The *in vitro* system used is a tissue culture correlate of experimental autoimmune orchitis⁸. In mixed cultures of fresh lymphocytes and autologous, trypsin dissociated testis cells, lymphoblasts appear within 4-5 d, which can induce progressive orchitis when reinjected into syngeneic recipients⁸, and *in vitro* specifically destroy syngeneic target cells (H.W., unpublished).

Following the protocol outlined in Fig. 1, I isolated the autoreactive lymphoblasts and allowed them to revert back to small secondary lymphocytes. The cellular events taking place in secondary EAO cultures, containing secondary lymphocytes plus relevant stimulator cells, are remarkable. In such cultures, large aggregates of lymphocytes and testis cells are formed within 12 h. Within 24 h of culture, most of the small lymphocytes have been retransformed into lymphoblasts. Cultures containing secondary EAO lymphocytes together with allogeneic testis cells, however, do not develop a demonstrable lymphocyte response.

These morphological events are exactly paralleled by the ³H-thymidine uptake observed in the cultures. The data in Table 1 represent one of six consecutive experiments. They demonstrate that L.BDV secondary lymphocytes which were primed against autologous testis cells respond strongly when exposed to syngeneic L.BDV testis cells.

Table 1 MHC specific restimulation of 2° lymphocytes which were primarily auto-sensitized against autologous testis cells

Stimulators in 2° cultures	Responder cells	
	Cell type	2° EAO-L.BDV lymphocytes
Testis	L.BDV	30'956 ± 2'380
	Lewis	4'305 ± 945
	L.BDV	114'507 ± 9'306
Lymphocytes	Lewis	13'485 ± 2'535
	Fresh L.BDV lymphocytes	1'510 ± 257
		2'247 ± 141
		1'834 ± 298
		6'305 ± 325

L.BDV lymphocytes were *in vitro* auto-sensitized against autologous trypsin dissociated testis cells. 2° lymphocytes which had been cultured for 11 d in the absence of external autoantigen were confronted in microtitre cells with syngeneic L.BDV and MHC-congenic (with different MHC, but identical genetic background) Lewis testis cells, and irradiated lymph node lymphocytes. In parallel cultures 1×10^6 fresh L.BDV lymphocytes were incubated with the four types of stimulator cells.

The same secondary lymphocytes do not react against allogeneic Lewis testis cells. These results demonstrate the immune specificity of the auto-sensitized secondary EAO lymphocytes. Furthermore, since L.BDV and Lewis rat strains are congenic with respect to their major histocompatibility gene complex (MHC), sharing an identical genetic background, and differ only at the MHC, these data, together with results obtained in other congenic combinations (for example, Table 2), suggest that MHC autoantigens have been recognised in the secondary reaction.

Unexpectedly, 2° EAO lymphocytes were not only re-stimulated by syngeneic testis cells, but also, to an even higher rate, by syngeneic lymph node cells (Table 1). Fibroblasts, on the other hand, did not elicit 2° responses. Two explanations may account for this phenomenon. First, lymphocytes may share cross-reacting autoantigens with testis stimulator cells. On the other hand, it is possible that the primary EAO reaction is the sum of two autoimmune components, one directed against testis cells, and the other against some cellular subpopulation among the lymph node cells. Accordingly, in the 2° reaction, the lymphocyte clones reacting with testis stimulators should be distinct from those activated by syngeneic

lymphocytes. Indeed, such 'spontaneous' reactions have been repeatedly described⁹⁻¹².

What is the nature of the autoantigens that elicit the secondary EAO reaction? The results shown in Table 1 suggest that antigens of the MHC are involved in the reaction. These H-1 antigens may be recognised in their native state, as 'unaltered self', by the secondary lymphocytes. On the other hand, these determinants may have been modified artificially by the culture procedures. In the latter case, the EAO reaction would correspond to lymphocyte reactions directed against syngeneic stimulator cells that have been altered either chemically¹³, by virus infection¹⁴ or by tumour transformation¹⁵.

The primary EAO reaction observed was directed against syngeneic testis cells which were dissociated by trypsin digestion. This treatment may either change normal surface antigens present on the surface membranes, or expose normally hidden determinants¹⁶. The finding that 2° cells primed with trypsin-digested testis cells can react optimally with syngeneic stimulator lymphocytes which have not been chemically treated at any time point, argues against this possibility. Moreover, a 2° reaction can also be readily initiated by testis cells that were mechanically and not enzymically dissociated.

Table 2 Lack of effect of heterologous culture sera on the specificity of the 2° reaction.

Stimulator cells	Horse serum	Serum additives Foetal calf serum
L.AS2	10,157 ± 764	10,752 ± 1,164
Lewis	1,210 ± 251	1,892 ± 191

L.AS2 lymphocytes were primarily autosenesitised against autologous testis cells, and reverted to 2° lymphocytes in the presence of horse serum. The washed 2° lymphocytes were tested for their immune specificity in the presence of either horse serum or foetal calf serum. The antigens in the 2° reactions were syngeneic or congenic freshly dissociated testis cells.

Another possible cause of 'self modification' may be the heterologous serum present in the culture medium. Several investigators have taken pains to show that horse serum contains components that will readily bind to mammalian cell surfaces^{17,18}. Such heterologous serum proteins could act as the foreign determinants required for an 'altered self' type of reaction. We tested this possibility by confronting 2° EAO lymphocytes (strain L.AS2), which had been cultured in horse serum medium, with syngeneic L.AS2 and MHC congenic Lewis stimulator cells either in medium containing horse serum, or, in parallel, in medium substituted with foetal calf serum. Medium supplemented with autologous serum could not be used, since this serum contains factors which specifically interfere with self recognition¹⁹. As shown in Table 2, the supplementing sera did not affect the specificity of the 2° reactions. Since it is probable that horse and foetal bovine serum proteins do not exhibit marked immunological cross-reactivity, alteration of MHC antigens by heterologous serum proteins does not seem to be a cogent explanation for the *in vitro* EAO. Moreover, it should be noted that, if foreign serum components played a critical role in the EAO reaction, the 2° lymphocytes, which possess normal amounts of MHC antigens themselves, should stimulate each other without the addition of any further target antigens.

Another possible explanation for self alteration is neo-expression of latent virus antigens on the stimulator cells. This possibility cannot be formally excluded at present and, indeed, there are claims that mouse lymphocytes can spontaneously express virus antigens after 24 h of culture²⁰. It should, however, be emphasised that in

secondary cultures the first signs of immune recognition and reaction against freshly isolated stimulator cells were noted within the first few hours of contact. This is a time span hardly sufficient for spontaneous and regular expression of virus antigens.

In conclusion, the data reported here lend further support to the notion that the normal immune system contains T lymphocytes, which are potentially able to react against the body's own tissues²¹. Our autoimmune memory system offers the opportunity to directly investigate the clonally enriched lymphocytes that possess receptors for autoantigen, and may thus be a valuable tool for elucidating the physiological mechanisms responsible for self tolerance at the T cell level. A final implication of our system is more of clinical relevance. Since the autoimmune secondary cells generated *in vitro* have the capacity to discriminate exquisitely between self and non-self, and since this capacity is not lost by storage in liquid nitrogen (unpublished), a similar, though modified, system might be helpful for human tissue typing. A particular advantage of this system is that the results of the reaction can be read after less than 24 h.

I thank Ms Marlot Prester and Ms Maria Luchmann for technical assistance, and Dr M. J. Weidemann for reading the manuscript.

Role of receptor aggregation in complement-dependent inhibition of lymphocytes by high concentrations of concanavalin A

EVIDENCE from haemolytic systems suggests that complement activation by either the classical or alternative pathways requires a close approximation of critical molecules at the cell surface. At least two molecules of IgG antibody in close proximity are required for the first component of complement to be bound¹. Thus when increasing concentrations of IgG are added to erythrocytes in the presence of excess complement, haemolysis is minimal until a critical IgG concentration is reached. In the case of the alternative (properdin) pathway of complement activation, at least two molecules of C3b must be critically orientated together at the cell surface in order for properdin to bind and stabilise C3/C5 convertase². Thus erythrocytes have a simple mechanism of signal discrimination by which they can 'count' the number of molecules reacting with their surfaces. The cells only 'respond' by lysis when a critical number has been reached.

I present data which relate this mechanism of signal discrimination by erythrocytes to the mechanism by which cultured lymphocytes discriminate between low and high concentrations of the mitogenic lectin concanavalin A (con A). This in turn may be related to the mechanism by which lymphocytes discriminate between low and high concentrations of specific antigen to produce either an immune response or immunological tolerance³.

Low concentrations of con A activate cultured rat lymph-node cells (enhanced incorporation of ³H-uridine), whereas high concentrations inhibit the cells by a complement-dependent process^{4,5}. The tetravalent con A molecules are able to aggregate surface receptors for con A on murine and human lymphocytes, but a divalent derivative, succinyl-con A, does not have this property⁶. Furthermore, although both forms of con A, at low concentrations, are able to activate lymphocytes to transform and incorporate ³H-thymidine after 2–3 d of culture, they differ in their effects at high concentrations. Lymphocyte transformation as assessed with ³H-thymidine is inhibited by high concentrations of the tetravalent molecule, but this is not found with the divalent derivative (see ref. 7 for review).

These results suggested that receptor aggregation might be necessary for the complement-dependent inhibition by high concentrations of tetravalent con A. To examine this hypothesis, the effects of various concentrations of succinyl-con A and con A were compared in the presence and absence of complement (bovine calf serum preheated at 56 °C for 30 min). The culture period was only 6 h and this would be expected to reduce the possibility that the cultured cells themselves could secrete complement components in quantities sufficient to influence the results⁸. The succinyl-con A was prepared from con A (Pharmacia) by the double derivatisation procedure described by Gunther *et al.*⁹.

Figure 1 shows that in unheated serum incorporation of ³H-uridine was stimulated at low con A concentrations but inhibited at high con A concentrations. The latter inhibition was not detected in cultures containing serum preheated at 56 °C. This confirms our previous results^{4,5}. In the case of preheated serum, the dose-response curve for succinyl-con A was similar to that for con A except for a small, but consistent, shift of the ascending limb to the right. In the case of unheated serum, the profound inhibition observed at high concentrations of con A was not observed at high concentrations of succinyl-con A. At such concentrations of succinyl-con A the curve plateaued at approximately the same level as the peak response of the curve for con A in unheated serum.

If receptor aggregation were necessary for the complement-dependent inhibition by con A, then both of the dose-response curves for succinyl-con A should have been similar to the curve for con A in heated serum. The depression of the plateau in the case of succinyl-con A in unheated serum suggests that our preparations of succinyl-con A still retain some complement-dependent inhibitory activity; but, even so, the inhibition was much less than that produced by tetravalent con A in unheated serum. Since the response to lectins is quantitatively dependent on the lectin : serum concentration ratio^{5,9}, a possible explanation for the shift of the ascending limbs of the curves for succinyl-con A to the right of those for con A, is that the capacity of serum to bind succinyl-con A is greater than its capacity to bind con A. Cells may also show a reduced binding capacity for succinyl-con A (refs 10, 11).

Although slightly higher concentrations may be required, succinyl-con A has the same capacity at tetravalent con A to activate lymphocytes, but has much less capacity to produce high dose inhibition. Since succinyl-con A produces less receptor aggregation ('patching' and 'capping') than con A, this suggests that such aggregation is not necessary for lymphocyte activation^{12,13}, but is necessary

for lymphocyte inhibition dependent on complement. In apparent conflict with this view is a report that, whereas 'low' concentrations of con A encourage receptor aggregation, 'high' concentrations impede receptor mobility and prevent aggregation¹⁴. Others have found, however, that 'high' concentrations of con A aggregate the receptors both of lymphocytes¹⁵ and of Chinese hamster ovary cells¹⁶. In the latter case cell death occurred. Since the effective concentration of con A depends on the con A : serum ratio⁵, some of these discrepancies may be the result of different serum concentrations employed by different workers. For example, Edelman *et al.*⁶ compared the con A dose-dependence of changes in receptor aggregation using lymphocytes in medium containing albumin (which binds con A weakly), with the con A dose-dependence of changes in cell proliferation using lymphocytes in medium containing serum (which binds con A strongly¹⁷). A concentration of con A which would have been effectively 'low' in the cell proliferation assay would have been effectively 'high' in the aggregation assay. Another apparent discrepancy in the literature is evident from reports that high-dose inhibition by con A is reversible^{18,19}. If complement is involved then such inhibition would be expected to be irreversible. There are a

Fig. 1 Comparison of con A dose-response curves (○, ●) with succinyl-con A dose-response curves (▽, ▼) for cultures containing serum which had been preincubated for 30 min at either 38 °C (open symbols) or at 56 °C (closed symbols). Lymph-node cells (2.1×10^6) from female Wistar rats were cultured as described before⁵ in 1 ml of medium containing bovine calf serum (20%), medium 199 (80%) and 1 μ Ci of 5-³H-uridine. After 6 h at 38 °C in a humidified atmosphere of air : CO₂ (95 : 5), cells were harvested for the determination of acid-precipitable radioactivity. Each point is the arithmetical mean of duplicate cultures. In the case of points presented without the standard error of the mean, the limits fell within, or close to, the area covered by the point. Values (c.p.m.) for control cultures without lectin (quadruplicates) were $10,425 \pm 357$ (serum preincubated at 38 °C) and $13,066 \pm 599$ (serum preincubated at 56 °C).

number of technical explanations for the discrepancy some of which have appeared in the recent literature^{20,21}. For example Moller²⁰ has pointed out that in earlier studies¹⁸ he and his co-workers had examined the mitogen-reactivity of cells surviving preincubation for a day with high con A concentrations; the lethal effect on the non-surviving cells had been ignored. In addition, heated calf serum was used; this would have reduced the extent of 'early-onset' inhibition (see below). Recently McClain and Edelman²² carried out similar studies with preheated calf serum. They presented evidence for 'delayed-onset' inhibition (see below) appearing after a day of culture at high con A concentrations. Again, however, attention was focused on the cells

able to survive the inhibition, rather than on the inhibition itself.

The role of complement in lectin-induced lymphocyte inhibition was predicted in 1966 but experiments at that time were negative²³. The eventual demonstration of the role of complement required the use of heterologous (bovine foetal or calf) serum rather than autologous serum^{4,5}. My recent studies indicate that complement inhibitors in autologous serum prevent the onset of the complement-dependent inhibition until after the first day of culture; addition of cobra venom factor to activate the alternative (properdin) pathway can apparently by-pass these complement inhibitors and make complement components available in autologous serum to mediate the inhibition by high con A concentrations in the early hours of culture²⁴. If heterologous serum is preheated the complement-dependent inhibition is not seen in the early hours of culture (Fig. 1). However, an inhibition appears after the first day of culture⁵; we have speculated⁵ that such inhibition requires the secretion of complement components by the cultured cells⁵.

In summary, I have shown that the previously reported failure of high concentrations of succinyl-con A to inhibit lymphocytes as assessed by ³H-thymidine incorporation after 2–3 d of culture⁶ is also demonstrable during the first few hours of culture (³H-uridine incorporation). While the inhibition by tetravalent con A, as assessed with ³H-thymidine, has neither been proven nor disproven to require complement (either present in serum or secreted by cells⁵), the inhibition occurring early in culture has been shown to be complement-dependent^{4,5}. My data thus support the hypothesis that divalent succinyl-con A does not inhibit because it is unable to produce the degree of aggregation of certain molecules at the cell surface which is necessary for complement-dependent inhibition. New techniques, such as resonance energy transfer²⁵, now permit a more detailed examination of the effects of con A and its derivatives on receptor distribution. It would be of interest to correlate the results of such studies with the degree of complement-dependent inhibition at a given con A concentration.

I thank Professor G. M. Edelman for review of the manuscript and Ms H. Turcotte for technical assistance. The work was supported by the MRC of Canada.

Use of ionophore A23187 to measure and to control free and bound cytoplasmic Mg in intact red cells

CYTOPLASMIC magnesium, whether free or complexed to nucleotides, has a fundamental physiological role as an essential cofactor for many cell enzymes, particularly those concerned with glycolysis, respiration and membrane transport. Various ingenious procedures have been applied to estimate^{1,2} or simulate^{3,4} intracellular conditions in relation to Mg but, because it is impossible to assess and control Mg²⁺ in the intact cell, most research on Mg requirements for metabolism and transport has used lysed cells⁵ and broken membrane preparations^{6,7}, which have inherent uncertainties about true concentrations and sidedness of effects. Using a divalent cation ionophore⁸ and a newly developed method^{9,10} we have investigated Mg buffering in intact human red blood cells and have found that the fresh, oxygenated, inosine-fed cell (a condition frequently used for ion transport studies^{11–14}) has three main buffer systems which bind nearly 90% of the total Mg present inside the cell in physiological conditions.

Net Mg movements across the intact red cell membrane are unmeasurably slow. Buffering was therefore explored using a selective divalent cation ionophore, A23187, in the absence of other divalent cations. Incorporation of this ionophore into the red cell membrane renders the cell highly permeable to Mg (refs 9, 10) allowing rapid equilibration of Mg ions across the membrane and with the intracellular buffers. By investigating the equilibrium distribution of Mg at different external Mg concentrations (see Fig. 1) a buffering curve can be constructed (Fig. 2). At electrochemical equilibrium the distribution of Mg ions is given by

$$\text{Mg}_i^{2+} = r^2 \text{Mg}_o^{2+} \quad (1)$$

where Mg_i²⁺ and Mg_o²⁺ are the molal concentrations of ionised Mg in cell water and in the medium, respectively, and *r*² is the Donnan distribution ratio for divalent cations at equilibrium. This is related to the membrane potential (*V*_m) by the expression *r*² = exp(–2*FV*_m/*RT*), based on the assumption that the activity coefficients of Mg are identical on both sides of the membrane. The total Mg content of the cells is the sum of the free and bound forms

$$\text{Mg}^T = \text{Mg}_i^{2+} + \text{Mg}^B \quad (2)$$

where Mg^T and Mg^B are the molal concentrations of total and bound Mg in cell water. From equations (1) and (2) we obtain

$$\text{Mg}^B = \text{Mg}^T - r^2 \text{Mg}_o^{2+} \quad (3)$$

The total Mg content of the cells was measured by atomic absorption spectroscopy (Pye–Unicam, SP 90) in the trichloroacetic acid supernatant of cell lysates. In order to estimate Mg^T, Mg^B and *r*², the cell water content and the membrane potential were determined at each Mg concentration, since we had found in preliminary experiments that the relatively large shifts in internal Mg concentration induced in the present experiments had an effect on cell water and on the concentration of non-diffusible anion responsible for the Donnan potential. Cell water was measured as the difference between wet and dry weights of packed-cell samples corrected for extracellular fluid using ⁶⁰Co³⁺–EDTA (ethylenediamine–NNN'N'–tetra-acetic acid) as a marker. The membrane potential was estimated from the ³⁶Cl distribution ratio¹⁵ at equilibrium, *r* = Cl_o[–]/Cl_i[–],

where Cl_o^- and Cl_i^- are the molal concentrations of Cl^- in the external solutions and cell water, respectively (for details see Fig. 1).

The concentrations of internal Mg at equilibrium with different external Mg levels are shown in Fig. 1. The equilibrium distribution of Mg was unaffected by the concentration of ionophore used, indicating that the ionophore neither contributed to nor affected the buffering of Mg by the cell.

Figure 2 shows the results obtained in four different experiments where the equilibrium concentrations of bound Mg (Mg^B) obtained from Fig. 1 and equation (3) are plotted as a function of Mg_i^{2+} . Although the data are not precise enough to allow a fine distinction between individual buffers or between various similar hypothetical models, the simplest model giving a good fit requires the presence of at least three different intracellular buffer systems: (1), about 100 μ mol per kg cell water of very high affinity buffers which are already saturated with Mg when Mg_i^{2+} is about 3×10^{-8} M; (2), about 2 mmol per kg cell water of high affinity buffers, apparent dissociation constant ~ 25 –50 μ mol per kg water; and (3), a large capacity, low affinity buffer system which may bind >1 mol Mg per mol of buffer. About 28 mmol per kg water of a buffer with an apparent dissociation constant ~ 4 mM fits the upper points reasonably well, but the fit of the lower points is improved if this component is attributed a capacity of ~ 20 mmol per kg water and two binding sites with apparent dissociation constants ~ 1 mM.

The original Mg content of the cells used in the present experiments was 3.46 ± 0.05 mmol per kg cell water. From curves such as those in Fig. 2, the Mg_i^{2+} at equilibrium with any value of Mg^T can be obtained. In this way the Mg_i^{2+} in the

Fig. 1 Mg content of cells as a function of time at different external Mg concentrations in the presence of the divalent cation ionophore A23187. Red cells from fresh blood were washed three times with about 10 vol of a solution containing NaCl, 75 mM; KCl 75 mM; Tris-Cl (pH 7.5 at 37 °C) 10 mM; and Tris-EGTA (1,2-di(aminoethoxy)ethane-*NNN'*-tetra-acetic acid) 0.1 mM and three more times with the same solution containing only 0.01 mM or no Tris-EGTA. After washes 0.25 ml of packed cells (2,000g for 5 min) were added to 2 ml of a similar medium also containing inosine (10 mM) and various concentrations of Mg and Tris-EDTA, to yield, together with Mg displaced from the cells, the final concentration of Mg_o^{2+} quoted on the figure. Before addition of ionophore, a 0.1-ml sample was taken to measure the original Mg content of the cells. At $t = 0$, 10 μ l of absolute ethanol containing 1 mg ml⁻¹ of ionophore A23187 were added to the cell suspension under vigorous magnetic stirring. At the times indicated 0.1-ml samples were withdrawn and the cells quickly separated through *n*-butyl-phthalate (BDH; density 1.042–1.045) as described previously^{9,10}, lysed in distilled water, the proteins precipitated with TCA and the Mg concentration measured in the supernatant. Water content and the ³⁶Cl distribution ratio, r , were measured as described in the text and their values are shown. The water fraction (f) is expressed as the weight of evaporated water per unit volume of packed cells. The volume of the extracellular fluid was $2.25 \pm 0.03\%$ of the volume of the cell pellet. The external concentration of Mg_o^{2+} at equilibrium was estimated from the nominal concentrations of Mg and EDTA in the original medium and the redistribution of intracellular Mg. The nominally Mg-free medium contained 2 mM Tris-EDTA and no added Mg; at equilibrium, Mg_o^{2+} was about 1.5×10^{-8} M and Mg_i^{2+} about 3×10^{-8} M. Variations in the external Na and K concentrations, and preincubation of the cells with inosine (variations used as part of other studies on the Mg dependence of active Na transport which will be reported elsewhere) had no effect on the Mg distribution. For clarity, only representative values for each concentration range are shown on the figure. The equilibrium concentration of intracellular Mg was measured for various lengths of time in different experiments (up to 60 min). The initial time course is only given for the extreme values of the Mg concentration range. With the ionophore concentration used in the present experiments, the half time to reach equilibrium was about 2.5 min.

Fig. 2 Equilibrium concentration of bound Mg as a function of the free Mg concentration in cell water. Mg^B was calculated from equation (3) and using the values of Mg^T , r and f shown on Fig. 1. Different symbols correspond to different experiments. The curves correspond to the theoretical equation $Mg^B = C_0 + C_1 (Mg_i^{2+} / (K_1 + Mg_i^{2+})) + C_2 (Mg_i^{2+} / (K_2 + Mg_i^{2+}))^n$ with C and K , in mmol per kg cell water; n is dimensionless. —, $C_0 = 0.1$; $C_1 = 1.5$; $C_2 = 28$; $K_1 = 0.04$; $K_2 = 4$ and $n = 1$; ---, $C_0 = 0.1$; $C_1 = 1.8$; $C_2 = 20.5$; $K_1 = 0.03$; $K_2 = 1$ and $n = 2$.

original cells was estimated at ~ 0.4 mM which is only slightly lower than that measured with a Mg electrode in a stroma-free, freeze-thaw lysate of oxygenated red cells (0.5 mM (ref. 3)).

At present we can only speculate about the nature of the different buffers. The minute fraction of tightly bound, acid-labile Mg may be associated with cytoplasmic components or with the membrane. Analysis of membrane fragments, however, may prove misleading because this binding can be affected by the separation procedure. It is interesting to note that these binding sites cannot be accessible to Ca (refs 9, 10).

Berger *et al.*³, using simulated intracellular conditions but a much reduced haemoglobin level, estimated the dissociation constants of the complexes of Mg with ATP and 2,3 bisphosphoglycerate (DPG) as 83 μ M and 1.67 mM respectively. It is tempting to equate the low and high affinity buffers reported in this study with DPG and ATP respectively. It is difficult, however, to account for the high capacity of the low affinity buffer even in inosine-fed cells, where the levels of DPG are high^{16,17}, unless other intermediates of the glycolytic pathway or haemoglobin, which did not bind Mg *in vitro*³, are also involved. In oxygenated cells, little ATP or DPG is bound to haemoglobin so that displacement of Mg buffers from haemoglobin by high Mg concentrations would be minimal; however a progressive decrease in the internal magnesium activity coefficient at high internal Mg would have the effect of reducing the calculated amount of low affinity buffer and this possibility cannot be ruled out at present.

The method described here can be used to investigate the effect of metabolism and deoxygenation on the Mg buffer curve in intact cells as well as the Mg dependence of active Na and Ca transport.

We wish to thank the Wellcome Trust Foundation and the MRC for funds to V.L.L., the Lilly Research Centre Limited for a gift of the ionophore A23187, S. B. Hladky and A. M. Brown for comments and for reading the manuscript and Mrs Gray for technical assistance. P.F. is an MRC Scholar.

Transient pressure changes in Donnan systems displaced from equilibrium

PRESSURE gradients at interfaces of porous membranes can be caused by two factors: (1) discrete changes in concentrations of particles which are excluded from the aqueous pores because of their size, and (2) electrical stresses which are caused by the action of an electric field on the charged particles at the membrane-solution boundary (A.I., theoretical results to be published elsewhere). Only the first factor is important in neutral pore-containing membranes;

the second operates at the boundary of charged pores, that is, in ion exchange membranes.

One of the consequences of theoretical work (A.I., unpublished) applies to Donnan systems. A Donnan system comprises a membrane interposed between two electrolytic solutions one of which contains impermeant polyelectrolyte particles. At equilibrium, the pressure developed across the membrane equals the difference between the osmotic values of the two solutions. The latter is greater than RTC_i , where C_i is the concentration of the impermeant polyelectrolyte on one side of the membrane^{1,2}, and R and T have their usual meanings. The higher pressure develops in the system because of the increase in concentration of the impermeant polyelectrolyte particles at the membrane solution interface, brought about by the presence of an electric potential profile at that region. Solution of the Poisson-Boltzmann equations for the interfacial region (see, for example, ref. 3) shows that, at equilibrium, the concentration of the impermeant particles at the pore-solution boundary, C_i^b , is such that RTC_i^b is equal to the difference between the osmotic values of two solutions.

Since the extent of accumulation of the polyelectrolyte at the membrane-solution boundary is a function of the salt concentration in the same solution, theoretical considerations lead to the following peculiar prediction: addition of salt to the side of the membrane which contains the polyelectrolyte would cause an immediate decrease in the pressure difference between the two sides of the membrane, even though the salt addition led to an immediate increase in the difference between osmotic values of the two solutions. Thus, phenomenologically the system would behave as if the reflection coefficient for the salt were negative. The experiments described confirm that prediction.

The diffusion cell (Fig. 1) consisted of two lucite chambers held in a metal frame. The flat outer margins of each chamber were cast with a Teflon lining and the membrane between the two chambers was sealed by being pressed on

Fig. 1 The diffusion cell. 1, Metal frame; 2, fastening screw; 3, open to room pressure; 4, Teflon lining; 5, stainless steel support; 6, membrane separating the two chambers; 7, plastic screws; 8, syringe needles through the centre of the screws (7); 9, heat-shrinkable Teflon tube; 10, three-way stopcock.

its outer circumference by the Teflon O-shaped linings. On the side of the membrane with the lower pressure, a perforated stainless-steel support (0.5 mm thick) was added. Forty per cent of the support area was perforated. One chamber of the diffusion cell (left in Fig. 1) was sealed as follows: two openings in the upper part of the cell were locked by plastic screws and, to ensure hermetic sealing, the outer rim of the screws were lubricated by high-vacuum silicon grease. Through the centres of these screws, syringe

needles were tightly secured into the chamber. The other end of the needle was connected to a heat-shrinkable Teflon tube. The solution was introduced into the chamber through one of the Teflon tubes. Manipulations of the chamber ensured complete filling of the chamber with the solution. After filling, one Teflon tube was connected to the pressure transducer and the other was clamped. The other chamber (right in Fig. 1) was open to room pressure and was directly filled with the desired solution. Mixing in both chambers was effected by magnetic stirrers and the experiments were conducted at room temperature (24–26 °C). A Statham pressure transducer (Model P23AC) and a Beckman recorder (Type R dynograph) were used. The time constant of the response of the transducer to pressure changes was instantaneous compared with that of the whole diffusion cell system, which was about 3 min.

Analytical procedures included chloride analysis by titration with mercuric nitrate using phenylcarbazone as an indicator, and sodium analysis by flame photometry. Several combinations of membranes and polyelectrolyte were tried. The characteristics required of the membrane were: relatively long aqueous pores, freely permeable to small ions, but completely impermeable to the polyelectrolyte. It was important to use only symmetric membranes. Membranes in which only a thin skin was the selective barrier were obviously unsuitable for this study. The best combination that we found were porous vinyl membranes (Nalco Chemical Company, Chicago) and a sulphonated dextran, of molecular weight of about 500,000 (Sigma Chemical Company, Saint Louis). The thickness of the membranes was $\sim 100 \mu\text{m}$ and the estimated pore diameter about $60 \text{ \AA}$.

The equilibrium pressure characteristics of the system are shown in Fig. 2. The calculated osmotic values of the dextran-containing solution as a function of the chloride

Fig. 2 The equilibrium properties of the diffusion cell when side I of the cell contained sulphonated dextran 9 mg ml^{-1} ; side II contained NaCl only. ---, Calculated osmotic value of the dextran solution as function of chloride concentration $[\text{Cl}]$. The osmotic value of side I was equal to that of side II plus $\Delta P/RT$. The osmotic value of side II was determined by multiplying the chloride concentration by 2 and by the activity coefficient of NaCl at the relevant concentration. The polyelectrolyte solution without chloride contained about 0.018 mM sulphonated dextran and 42 mM sodium. The fact that the osmotic value of the dextran solution is $\sim 8 \text{ mOsm}$ indicates that activity coefficient for Na is ~ 0.2 . Δ , $\Delta P [\text{Cl}]_I$; $\blacktriangle$, $\Delta P [\text{Cl}]_{II}$.

Fig. 3 Time course of change in pressure (Δ , $\blacktriangle$) in a Donnan system brought about by the addition of salt to either side of the cell. *a*, Addition to the sulphonated dextran solution; *b*, addition to the salt solution. Inset, Type of change that was effected at time zero (0_+). The initial conditions (0_-) were the same in both cases. ---, Difference in osmotic values of the two solutions as determined by the chloride concentration in both sides, $\square$, $\blacksquare$, derived by direct chloride analysis; $\circ$, $\bullet$, osmotic values based on calculations of chloride concentrations. $[\text{Cl}]_I$ was estimated from the concomitant ΔP measurements making use of the relevant curve in Fig. 2; $[\text{Cl}]_{II}$ followed from the principle of conservation of matter. The vertical lines represent upper and lower limits which resulted from uncertainties in chloride analysis ($\pm 0.1 \text{ mM}$) and in ΔP measurement ($\pm 0.5 \text{ cm H}_2\text{O}$).

content are also shown in Fig. 2. Chloride was added to the dextran solution as NaCl. The pressure changes accompanying NaCl addition to either side of the system are shown in Fig. 3.

The dashed lines in Fig. 3 represent the difference between osmotic values of the solutions on the two sides of the membrane and curves *a* show that the addition of NaCl to the polyelectrolyte solution lead to increase in the difference between the osmotic values of the two solutions and to decrease in the pressure difference across the membrane.

The results of Fig. 3 could also be accounted for by the assumption that a significant unstirred layer occurs in the side of the membrane which had the metal support. To account for the results along these lines, however, needs an assumption that Donnan equilibrium was attained instantaneously across the membrane and that the diffusion barrier was located only on the side which did not contain the sulphonated dextran. Therefore we have conducted NaCl diffusion experiments through the system with and without the perforated metal support. These experiments demonstrated that the permeability of the membrane to NaCl was 20–30% greater when the metal support was used, probably because the effective membrane area was a little more than the porous area of the metal support. At any rate, these experiments proved clearly that unstirred layers could not constitute a significant barrier in the diffusion cell. The membrane permeability to NaCl was $\sim 3 \times 10^{-4} \text{ cm s}^{-1}$. This level of permeability would correspond to unstirred layer of about $330 \mu\text{m}$ thickness. Analysis of thickness of unstirred layers as a function of stirring rates shows that

they vary from $\sim 75 \mu\text{m}$ at slow rate of stirring to $50 \mu\text{m}$ at vigorous stirring⁴. Thus, it is unlikely that an unstirred layer had a major effect in the system described here.

We suggest that these experiments support the notion (A.I., unpublished) that the pressure across the porous membrane is determined by the concentration of the impermeant polyelectrolyte particles at the membrane solution interface. The extent of accumulation of the polyelectrolyte molecules at the membrane interface is a function of the salt concentration in the solution. At equilibrium, that is, in classical Donnan systems, the accumulation of the polyelectrolyte molecules at the membrane interface gives rise to a pressure difference which is exactly equal to the difference between the osmotic values of the two solutions.

Functional striated muscle cells from non-myoblast precursors following 5-azacytidine treatment

5-AZACYTIDINE (aza-CR)—a *s*-triazine nucleoside analogue of cytidine—has strong inhibitory effects in various biological systems including neoplasms: it is a powerful bacteriostatic, antitumour and mutagenic agent¹. Aza-CR also exhibits immunosuppressive, antimitotic, radioprotective and virostatic effects¹. The cytostatic effect of aza-CR has primarily been directed against leukaemia² and it has been used to treat human solid tumours³. During a study on the morphological transformation of C3H 10T $\frac{1}{2}$ C18 cells by cancer chemotherapeutic agents, it was noted that elongated multinucleated cells arose in cultures exposed to aza-CR⁴. The C3H 10T $\frac{1}{2}$ C18 line is a clonal line of mouse embryo cells developed at the McArdle Laboratory for Cancer Research for use in studies on chemical oncogenesis *in vitro*⁵⁻¹⁰. The cells are highly sensitive to post-confluence inhibition of cell division, show a remarkably low rate of spontaneous transformation and grow with a fibroblast-like morphology with long cytoplasmic processes in sparse cultures. When confluent, they form flat even monolayers and appear epithelioid. Scanning electron microscopy has shown the confluent cells to be extremely thin and polygonal with smooth surfaces resembling epithelial cells¹¹. Here we describe experiments showing that the multinucleated tubular cells which arise in C3H 10T $\frac{1}{2}$ C18 cells treated with aza-CR are in fact functional myotubes.

The formation of a large focus of multinucleated cells in a culture of C3H 10T $\frac{1}{2}$ C18 cells treated with aza-CR is shown in Fig. 1a. The long tubular characteristics of the cells growing on a monolayer of mononucleated cells should particularly be noted. These tubular cells contained many nuclei with distinct nucleoli (Fig. 1b). The background of C3H 10T $\frac{1}{2}$ C18 cells can also be seen.

In some such cells, regular striations were apparent (Fig. 1c), with a repeating unit length of $2.7 \mu\text{m}$. The striations were a feature which appeared shortly after the formation of the multinucleated cells about 9-10 d after treatment with aza-CR. Although the multinucleated cells sometimes persisted for up to 20 d after their appearance, most of them started to atrophy soon after they were

Fig. 1 Myotubes induced in C3H 10T $\frac{1}{2}$ C18 cells by aza-CR. a, Low magnification ($\times 69$) of a living culture showing a focus of multinucleated cells. b, Phase contrast microscopy of a living culture showing many nuclei with distinct nucleoli in a multinucleated cell. The background of evenly-distributed nuclei of the C3H 10T $\frac{1}{2}$ C18 monolayer can also be seen ($\times 252$). c, Phase contrast microscopy of a living culture showing clearly defined, regular striations ($\times 546$).

formed and not many remained longer than 14 d. Table 1 lists some of the physical characteristics of these cells. They are macroscopic and many can be seen with the naked eye. They are generally long and thin, being on average 20 times longer than they are thick. The tubular cells are found either isolated or in foci (for example, Fig. 1a); however, the majority of multinucleated cells are found in foci. There is a large variation in the number of nuclei per cell, ranging from 2 to approximately 2,000, the average being 8.6 nuclei per cell.

A small percentage of the multinucleated cells have occasionally been seen to contract spontaneously or twitch in culture about 7 d after their appearance. This twitching continued for various lengths of time, between 1 and 7 d depending on the stage of atrophy of the cells. Twitching was generally seen in the middle or late atrophy stages of

We consider these cells which arise in aza-CR treated cultures to be muscle cells for the following reasons: (1) The cells are multinucleated and tubular in morphology. (2) Striations are evenly and regularly spaced and found to be 2.7 μ m long. (3) Spontaneous contractions of the cells have been seen in several experiments. (4) The cells

Table 1 Physical characteristics of multinucleated tubular cells arising in aza-CR-treated cultures

Character	Average value	Range	No. of cells examined
Length	0.9 mm	0.16–3.96 mm	23
Width	0.043 mm	0.007–0.37 mm	23
No. of nuclei per cell	8.6	2–2,000	736
Twitching rate	88 contractions per min	55–160 contractions per min	14

The measurements were made on fixed and stained dishes with the exception of the twitching rate which was determined in living cultures.

the life of multinucleated cells, and the twitching rate shown in Table 1 varied from 55 to 160 contractions per min. The twitching was generally localised to small areas of the cells, although waves of contraction have been seen to pass through a length of a focus in one case.

Cells possessing striations have been artificially stimulated to contract with acetylcholine. This was done by placing a drop of 1 mM acetylcholine over the cell in question while observing it with the inverted microscope. This technique was not successful in every instance but some tubular cells contracted strongly and then remained in the contracted state.

The effect of aza-CR was markedly dependent on the concentration of analogue used (Table 2). Little cytotoxicity, as measured by decrease in plating efficiency, was seen with a level of 3.0×10^{-7} M aza-CR and a few multinucleated cells were formed. A concentration of 10^{-6} M aza-CR, however, caused appreciable cell death while there was a very large increase in the number of nuclei appearing in multinucleated cells. A dose of 3.0×10^{-6} M aza-CR was considerably more cytotoxic (80% decrease in plating efficiency) and fewer nuclei appeared in tubular cells. But, when a correction was made for the extent of cell killing, this dose was also effective in inducing the formation of multinucleated cells. Table 2 also shows that the intact triazine ring of aza-CR is necessary for this effect. The ring is rapidly hydrolysed¹² at slightly alkaline pH and we found the half-life of aza-CR to be about 90 min at 50 °C in phosphate-buffered saline at pH 7.4. When the stock solution was kept at this temperature for 20 h it lost its ability to cause cytotoxicity and multinucleation. Finally, it should be noted that there are approximately 600,000 mononucleated cells in the dishes at confluence so that the percentage of nuclei appearing in tubular cells is relatively small even under optimum conditions.

respond positively to acetylcholine which points to the presence of functional acetylcholine receptors. None of these properties has been found in untreated C3H 10T $\frac{1}{2}$ C18 cultures or in cultures treated with many other agents. Furthermore there is no other evidence to suggest that the line is myoblastic in nature^{5,11}. It is unlikely that aza-CR selects for possible myoblast contaminants in the parent line since these effects have been found in a laboratory where myoblasts were not grown⁴ and multinucleated tubular cells are never seen in untreated controls. An additional point is that the multinucleated cells were induced in two separate batches of C3H 10T $\frac{1}{2}$ C18 cells which were obtained from the McArdle laboratory. The effects of aza-CR are reproducible although we have found variations in the absolute numbers of fused nuclei in different experiments.

We therefore conclude that the production of muscle cells was induced by aza-CR. Piled-up foci of other cell types were also formed following treatment with aza-CR. We are currently attempting to characterise them, since it is possible that other types of phenotypic conversion may also occur.

Two possibilities for the origin of the multinucleated cells are (1) endoreduplication and (2) fusion of many mononucleated cells. Preliminary photographic experiments have shown many bipolar mononucleated cells in areas where multinucleated cells subsequently appeared suggesting that fusion was occurring. It seems, therefore, that aza-CR causes regulatory changes in the C3H 10T $\frac{1}{2}$ C18 cells which leads to some of them becoming myoblasts. The precise cell type from which the C3H 10T $\frac{1}{2}$ C18 cell is derived is not known, but this information will be of value in assessing the extent and the nature of the change induced by aza-CR. It seems possible, however, that the compound will be of value in studying differentiation in an analogous way to the use of

Table 2 Formation of multinucleated cells after treatment of C3H 10T $\frac{1}{2}$ C18 cells with aza-CR

Concentration of aza-CR (M)	Plating efficiency (%)	Average no. of nuclei in multinucleated tubular cells* per dish	No. of nuclei in multinucleated cells per 100 cells surviving treatment
0	25	0	0
3.0×10^{-7}	22	133	60
1×10^{-6}	13	4,624	3,557
3.0×10^{-6}	5	1,637	3,274
1×10^{-6} , preheated at 50 °C for 20 h	26	0	0

Stock solutions of aza-CR were made up fresh for each experiment in phosphate-buffered saline pH 7.4, sterilised by filtration and kept at 0 °C until used. C3H 10T $\frac{1}{2}$ C18 cells were used in the 15–20th passage and were grown in Eagle's basal medium supplemented with 10% heat-inactivated foetal calf serum and penicillin and streptomycin. Cells obtained from log-phase mass culture were seeded into 60-mm dishes (1,000 cells per dish) and treated 24 h later with the indicated doses of aza-CR. Exposure was for 24 h, after which the cultures were washed and maintained for 14–16 d. The dishes were then rinsed with water, fixed with methanol and stained with May/Grünwald and then Giemsa stains. The dishes (four per group) were then scored for nuclei in multinucleated cells at 100 $\times$ magnification. Cell killing was determined by the lowering of plating efficiency in similarly treated cultures containing 200 cells and stained with Giemsa stain after 10–12 d. Data given are the average values from two separate experiments.

*A multinucleated tubular cell was defined as an elongated cell having two or more nuclei.

5-bromo-2'-deoxyuridine¹³. In this regard it is of obvious interest that the analogue is incorporated into nucleic acids with a high efficiency¹⁴.

Voltage-dependent effect of curare at the frog neuromuscular junction

CONDUCTANCE measurements on various cholinergic post-junctional membranes have demonstrated voltage-dependent effects for acetylcholine (ACh) and its agonists¹⁻⁵, for local anaesthetics⁶, and for curare⁵. It is not yet clear which of the steps in drug-receptor interaction are rate-limiting for voltage-dependent effects of ACh. Kordaš⁷ considers this step to be the

Fig 1 Lower: Peak amplitude of the ACh potential (ordinate) plotted against the membrane potential (V_m , abscissa) for data obtained during the control period (Δ) and then, several minutes later, in the presence of $4.3 \mu\text{M}$ TC-Ringer ($\blacktriangle$). The membrane potential plotted is that value measured just before the beginning of an ACh potential. The amount of ACh released by iontophoresis was constant throughout, the total charge released per iontophoretic pulse being 4.37 nC . The data were obtained while the membrane was hyperpolarised away from and, then, repolarised back to the resting potential. Note that the ACh potential amplitude increased with hyperpolarisation while the preparation was bathed in normal Ringer but that it remained essentially unchanged during hyperpolarisation when curare was present. Upper: The input resistance of the muscle fibre (ordinate) is plotted against membrane potential. Measurements made before ($\circ$) and in the presence of curare ($\bullet$) show that the small degree of anomalous rectification¹³ observed in this fibre was unaffected by curare.

initial binding between ACh and its receptor, whereas Magleby and Stevens⁸ consider the conformational changes between open and closed states of the receptor to be rate-limiting. Distinct from the initial binding reaction and the subsequent conformational change is the possibility of a drug binding to a receptor that is in its open, rather than closed, state, thereby forming a complex consisting of three molecular species. This idea comes from Steinbach's model⁹ for the action of local anaesthetics at the frog endplate. Such multi-molecular complexes have been included in reaction schemes which describe voltage-dependent effects for local anaesthetics at the frog endplate¹⁰ and for curare in *Aplysia* neurones⁵. Marty *et al.*⁵ found that during hyperpolarisation of molluscan neurones, curare became a more effective blocker of the response to slowly applied ACh. Such an effect of curare was not seen when ACh was applied quickly to the receptors, that is when there was insufficient time for ACh to equilibrate with its postsynaptic effect. They suggested that the binding between curare and the cholinergic receptor is

Fig. 2 Reversibility of the increased blocking effect of curare during hyperpolarisation. Six oscillograms (a-f) were obtained sequentially from the same endplate. Three CRO traces are present in each oscillogram. Upper trace, hyperpolarising current (inward current, downward) applied to the fibre from an intracellular microelectrode. Middle trace, intracellular recording of membrane potential. Lower trace, iontophoretic current (outward current, upward) through the ACh pipette. (Arrows point to the tops of the ACh current pulses in b and e.) a-c: ($4.3 \mu\text{M}$ TC present) A response was first obtained at the resting potential (a). The ACh potential decreased during hyperpolarisation (b) and returned to its control value when ACh was applied again at the resting potential (c). The preparation was then washed with curare-free Ringer, and about 2 min later, the recordings in d-f were obtained. The amount of ACh released by iontophoresis, held constant in a-c, was decreased until the amplitude of the ACh potential in d was about equal to that in a. The ACh potential increased with hyperpolarisation (e). The resting potential was -63.4 mV . Total charge released from ACh pipette: a-c, 18.0 nC ; d-f, 5.74 nC . Horizontal calibration: 400 ms . Vertical calibration: 100 nA (membrane current); 40 mV (V_m); 200 nA (iontophoretic current).

voltage-dependent but that this particular kind of binding can only occur between curare and a receptor which is already in its open state. Here I show that curare has a very similar effect at the frog neuromuscular junction. The efficacy of curare as a postsynaptic blocker at the frog neuromuscular junction increases when the muscle fibre is hyperpolarised. This effect is seen only when ACh is applied slowly, however, and not when it is applied rapidly during neural release of ACh.

Experiments were performed at room temperature ($19-23^\circ\text{C}$) on sartorius muscles from *Rana pipiens*; in some experiments, nerve muscle preparations were used. The composition of the normal Ringer (mM) was: 111 NaCl ; 2.5 KCl ; 2.0 CaCl_2 ; $0.4 \text{ NaH}_2\text{PO}_4$; $1.1 \text{ Na}_2\text{HPO}_4$ (pH 6.9). Conventional procedures were used for applying ACh by iontophoresis^{11,12}, for recording membrane potential with an intracellular microelectrode (containing 1 M potassium citrate), and for changing membrane potential by passing constant current pulses through a second intracellular microelectrode. The ACh pipettes had tip diameters

of about 1 μm and electrical resistances of 30–60 M Ω . The oscillograms shown in Fig. 2 are representative of the duration of the constant current pulses used to change the membrane potential and the time course of the responses to iontophoretically applied ACh (ACh potentials). ACh was applied at 15-s intervals. The responses to iontophoretically applied ACh were always much slower (by a factor of about 50–100) than were those due to ACh released from nerve terminals.

Figure 1 shows an experiment in which the amplitude of the ACh potential was measured at various membrane potentials with and without 4.3 μM tubocurarine (TC). In the absence of curare the ACh potential increased together with the driving force as the muscle fibre was hyperpolarised. In the presence of curare, however, the ACh potential, quite unexpectedly, did not increase with hyperpolarisation. This phenomenon is reversible in two respects. First, the increased action of curare was only seen during hyperpolarisation (Fig. 2b); it was not seen when the hyperpolarising pulse was no longer applied (Fig. 2c). Second, when the curare was removed by washing with curare-free Ringer (Fig. 2d–f), the phenomenon was no longer observed (Fig. 2e).

The voltage-dependent effect of curare shown in Figs 1 and 2 is not simply an apparent effect resulting from errors inherent in the measurement of postsynaptic potentials due to the non-linear electrical characteristics of the muscle fibre¹³ and/or to the fact that the instantaneous driving force actually decreases during a postsynaptic potential. Previous work¹⁴ and data from this study (Figs 1 and 2 b, e) show that curare does not affect the electrical properties of the nonsynaptic membrane. In addition, when the iontophoretic current was adjusted so that ACh potentials of almost equal amplitudes were obtained at the resting potential both in the presence and absence of curare (Fig. 2 a, d), the ACh potential decreased during hyperpolarisation only when curare was present (Fig. 2b).

Fig. 3 Comparison of the effects of hyperpolarisation on the ACh potential and e.p.p. in the presence of curare. The amplitudes of the postsynaptic potentials due to the iontophoresis of ACh (ACh potentials, $\blacktriangle$) and to the synchronous release of ACh quanta from nerve terminals (e.p.p.s, $\blacksquare$) are plotted on the ordinate against membrane potential (abscissa). All data are from the same endplate. 3.6 μM TC was present. The ACh potentials and the e.p.p.s were recorded on alternate sweeps as the muscle fibre was hyperpolarised. Either the nerve was stimulated or ACh was applied by iontophoresis approximately 400 ms after the start of a hyperpolarising pulse. The e.p.p. increased with hyperpolarisation, as expected, while the ACh potential decreased. The increased action of curare with hyperpolarisation was not seen with neurally released ACh; this action was only observed when ACh was applied more slowly to the receptors by iontophoresis. In this experiment, the input resistance decreased from 800 k Ω during minimal hyperpolarisation to 400 k Ω during maximal hyperpolarisation. Therefore, there is a possibility that, due to the complex electrical properties of the muscle fibre^{9,17}, anomalous rectification influenced only the slow ACh potential and not the fast e.p.p.

The simplest model to account for this voltage-dependent effect of curare would involve an increased binding between curare and the closed cholinergic receptor during hyperpolarisation. But, if that were true, then the response to ACh released from nerve terminals should also reflect this increased binding of curare. The work of Takeuchi and Takeuchi¹⁵, and data in Fig. 3 show that such a voltage-dependent effect of curare is absent in experiments dealing with the neural release of ACh. In the experiment shown in Fig. 3, simultaneous recordings were made of the endplate potential (e.p.p.; neural release of ACh) and the ACh potential (iontophoresis of ACh). During hyperpolarisation the e.p.p. increased in a manner similar to that seen for neurally evoked endplate currents¹⁵, while the ACh potential decreased.

Thus, we can reject the possibility that curare binds more effectively to the closed receptors during hyperpolarisation, and conclude that there must be two mechanisms for the action of curare. One mechanism is dependent on membrane potential and the other is not. The first mechanism is the classical one¹⁶ in which curare binds to the closed cholinergic receptor and competes with ACh for binding sites; the classical action of curare is voltage-independent. The second mechanism, described in this study (see also ref. 5), might involve curare binding to the ACh receptor after it has already undergone a conformational change. Since an ACh receptor undergoes a conformational change during its interaction with ACh, I suggest that it is the activated ACh receptor complex⁹ (open state of the receptor) to which curare can bind with increasing effectiveness during hyperpolarisation. The proposed reaction scheme, which is based on that given by Ruff¹⁰ for the effect of a local anaesthetic on ACh-receptor-interaction, is

where K_1 represents the initial binding between agonist and receptor, K_2 represents the conformational change to an open receptor (TR^*), and K_3 represents the voltage-dependent binding reaction between the open receptor and curare to form TR^*C . It is assumed that the conductance of TR^*C would be zero.

Neural release of ACh is so fast that ACh is not in an equilibrium with its postsynaptic effect, whereas such an equilibrium can be attained when ACh is slowly applied by iontophoresis^{1,18,19}. It is of interest to point out a similarity between the voltage-dependent effect for ACh (that in which the ACh-induced conductance increases with hyperpolarisation^{1–5,20}) and that for curare. Both effects are observed only under equilibrium conditions, that is, both are absent when ACh is released quickly from nerve terminals (Fig. 3; refs 1 and 15). One may then ask if similar mechanisms are involved. Thus, can an activated agonist-receptor complex bind slowly not only to local anaesthetics and to antagonists, but also to agonists?

Immune lesions of noradrenergic neurones in rat central nervous system produced by antibodies to dopamine- β -hydroxylase

THE development of antibodies against several neurotransmitter synthesising enzymes has facilitated immunohistochemical identification of specific neurones in the nervous system^{1,2}. The availability of these antibodies has also raised the possibility of producing immune lesions of the neurones in situations where the antibody has access to its antigen *in vivo*. In the case of synaptic vesicle antigens, the vesicle membrane becomes incorporated into the nerve terminal membrane during release of transmitter by exocytosis³⁻⁵. Dopamine- β -hydroxylase (DBH), the enzyme that synthesises noradrenaline, is located in the membrane of noradrenergic synaptic vesicles and would become exposed to antibodies in the extracellular space during nerve activity⁶. Binding of injected DBH antibodies has been demonstrated both histochemically and biochemically in sympathetic nerves⁷⁻⁹. Antibodies to DBH cause degeneration of noradrenergic nerve terminals in several guinea pig tissues when injected intravenously^{10,11}; this form of immunosympathectomy seems to be a complement-mediated reaction¹². We report here that injection of anti-DBH serum and complement into the cerebrospinal fluid (CSF) of rats produces degeneration of noradrenergic nerve fibres in the central nervous system.

Female Porton rats (200-250 g) were anaesthetised with intraperitoneal sodium pentobarbital (42 mg per kg body weight) and placed in a Kopf stereotaxic apparatus. A 21 or 23 gauge steel needle connected to a Harvard infusion pump was inserted stereotactically in either a lateral or the third ventricle. Rabbit anti-bovine DBH serum¹³ (50-250 μ l) mixed with complement (50-250 μ l of guinea pig serum) was infused over 1-2 h. Outflow of CSF and antiserum occurred from the subarachnoid space around the infusion site or from a cannula inserted in the cisterna magna. Nine rats received anti-DBH serum and complement and four control rats received equivalent volumes of non-immune rabbit serum and complement.

At times varying from 2 to 7 d after antibody infusion, rats were anaesthetised, a cannula inserted retrogradely into the abdominal aorta and the right atrium was cut. Perfusion was started with normal saline and continued for 1 h with 4% formaldehyde and 0.5% glutaraldehyde (electron microscopy grade) in 0.1 M sodium phosphate buffer, pH 7.0. This aldehyde mixture has recently been shown to fix the nervous system and simultaneously convert catecholamines to fluorescent derivatives¹⁴. The brain and upper spinal cord were removed, cut into 5 mm transverse slices, and 30- μ m sections cut on a Vibratome at 4 °C. The freshly cut sections were photographed at low magnification using transmitted white light and dried over phosphorus pentoxide for 1 h. The sections were then mounted in liquid paraffin or Fluormount and examined with a Leitz Ortholux II microscope, fitted with a high pressure mercury vapour lamp. Both control and experimental sections were studied immediately after preparation of the sections before fading of the finest terminals. The distribution of fluorescent, catecholamine-containing structures was mapped on prints of the original white light photographs¹⁴.

Many thick and distorted fluorescent axons were visible throughout the brains of all animals that received immune serum (Fig. 1a). They were most numerous in the medial septal nuclei, diagonal band of Broca, piriform cortex,

Fig. 1 a, Fluorescence photomicrograph of a transverse section through the zona incerta of a rat brain 3 d after anti-DBH serum and complement were infused into the third ventricle. Many obliquely sectioned noradrenergic fibres are thick and distorted. ($\times 165$.) Insert top right: a single degenerating axon in the same area. ($\times 400$.) Insert lower left: zone incerta of normal rat brain showing oblique sections of bundles of ascending noradrenergic axons. ($\times 165$.) b, Fluorescence photomicrograph of a transverse section through the hippocampus of a rat brain 3 d after non-immune serum and complement were infused into the lateral ventricle. Many normal varicose axon terminals are present. ($\times 330$.) c, A corresponding hippocampal area in a rat 3 d after anti-DBH serum and complement were infused into the lateral ventricle. The noradrenergic terminals are no longer apparent. ($\times 330$.)

rostral corpus callosum, zona incerta, posterior commissure, dorsal tegmental bundle and occasionally in fibre tracts in the lateral funiculi of the thoracic spinal cord. In contrast to the fine smooth appearance of normal catecholamine-containing axons, the degenerating fibres were very brightly fluorescent and irregularly swollen. In longitudinal sections the axons often appeared as a series of bulges connected by fine strands.

In addition to the swollen axon bundles, there was a patchy loss of varicose axon terminals accompanied by occasional swollen varicosities in the neocortex, hippocampus and cerebellar cortex (Fig. 1c). The catecholamine-containing cell bodies in the brain stem seemed normal. In the control rats, there was no detectable loss of varicose axon terminals (Fig. 1b) and the only swollen fibres seen were confined to the area of local necrosis along the pathway of the cannula.

The distribution of the swollen fluorescent fibres occurs within the general distribution of known noradrenergic fibre tracts¹⁵⁻¹⁷, and their appearance resembles that of degenerating noradrenergic axons in the peripheral nervous system induced by antibodies to DBH (ref. 10). The immune lesions are probably produced when antibodies bind to DBH exposed in the axon terminal membrane during exocytotic release of transmitter with subsequent lysis of the terminal membrane by complement fixed by the immune reaction¹². This destruction of axon terminals leads to an accumulation in preterminal axons of noradrenaline-synthesising vesicles transported from the neurone cell body⁶.

The lesions in the central nervous system are likely to be confined to noradrenergic and adrenergic neurones in which DBH is localised. The specificity of the antiserum used has been well defined by both immunochemical⁶ and immunohistochemical procedures¹⁰ and, in the peripheral nervous system, the degeneration produced by intravenously administered anti-DBH was confined to noradrenergic nerves¹². In principle, the use of an antiserum directed against a specific constituent of synaptic vesicle membranes could be extended to produce immune lesions of neurones using transmitters other than noradrenaline.

Possible role of pH gradient and membrane ATPase in the loading of sucrose into the sieve tubes

FOR plants to grow, sugars and other assimilates must constantly be transported from the leaves to the growing or storage regions. This essential transport function takes place in the highly specialised phloem tissue which consists of a network of interconnecting sieve tubes. In spite of its obvious agronomic importance, little is known about the first step of sugar entry (loading) into the sieve tubes. Here I propose a model which formulates several of the established, but difficult to reconcile, characteristics of the sieve tubes into a unifying model for sugar uptake. These characteristics include the alkaline sap¹ (pH 8-8.5) with a high potassium ion and ATP² concentration, the presence

Fig. 1 Model of transport into sieve tubes

of electrical gradients³ and the considerable ATPase⁴ activity of the sieve tube plasmalemma. According to this model, sucrose leaves the site of synthesis in the mesophyll cells and enters the free space or apoplast which has a pH of 5 to 6. The sucrose is then accumulated into the alkaline sieve tubes by an active process involving membrane sulphhydryl groups⁵. In this model the proton gradient of nearly 3 pH units across the sieve tube plasmalemma provides the driving force for sucrose uptake (Fig. 1). Based on non-electrolyte transport studies in bacteria⁶, algae⁷ and fungi⁸ it is proposed that protons are cotransported with sucrose into the sieve tubes.

The proton gradient across the membrane is maintained for continuous sucrose influx by an ATP-driven proton extrusion system wherein ATP is hydrolysed by the plasmalemma ATPase in such a way that an asymmetrical distribution of protons and hydroxyl ions is established across the sieve tube plasmalemma thereby maintaining the internal alkalinity. Studies on the cotransport of hexose and protons in the algae⁷ and fungi⁸ indicate that both a proton gradient and its resulting electrical potential are

involved in uptake. In this regard, it should be noted that potassium ions have been implicated in electrical gradients in the phloem³. Thus, it would be most valuable to establish the magnitude of any electrical potential difference across the sieve tube membrane during sucrose uptake.

Data on phloem loading of sucrose support the model. Using non-permeant buffers to change the pH of the apoplast, sucrose uptake into the sieve tube and translocation from the source leaf of an intact plant were inhibited when the magnitude of the pH difference between the apoplast and symplast was reduced⁹. The pH optimum for phloem loading is 5, and loading is markedly inhibited at pH 8. In addition, the affinity of the carrier for sucrose is decreased at pH 8. Thus, proton and sucrose molecules can bind to a membrane carrier which displays a higher affinity in the protonated form (Fig. 1). The charged complex (sucrose-H⁺-carrier) can be driven across the membrane by the electrical potential difference generated by the proton extrusion mechanism.

Echovirus 12-induced host cell shutoff is prevented by rhodanine

INFECTION of animal cells with picornaviruses results in inhibition of host cell RNA and protein synthesis shortly after infection, as was shown with members of the cardiovirus group¹⁻³, with poliovirus⁴⁻⁶, and with foot-and-mouth disease virus⁷. The molecular mechanism of this so-called shutoff is not well understood; however, it seems to require protein synthesis early in infection^{2,8,9}, but no viral RNA replication⁹⁻¹¹. We report here that 2-thio-4-oxothiazolidine (rhodanine), at a concentration which inhibits selectively the uncoating of echovirus 12 in GMK cells also inhibits the virus-induced shutoff of GMK cell protein synthesis.

The infection of GMK cells, a permanent cell line derived from African green monkey kidney cells¹², with echovirus 12 (prototype Travis) is followed by inhibition of the GMK cell protein synthesis to the extent of 80% by 3 h post infection (p.i.). A clear peak of viral protein synthesis is visible 4-5 h p.i. RNA synthesis declines more gradually, showing a specific shoulder 4-5 h p.i. due to viral RNA synthesis. At 3 h p.i. viral RNA and protein synthesis is not yet detectable in the conditions of our experiments and formation of new particles has not yet started¹².

Rhodanine acts by blocking uncoating of the virus without inhibiting virus adsorption or penetration¹². Nor does it affect the replication of purified echovirus 12 RNA in GMK cells. Furthermore, infective virus could be recovered quantitatively from infected, rhodanine-treated cells and rhodanine was shown to protect the echo 12 virion from alkaline degradation *in vitro*. Rhodanine apparently acts by stabilising the virion structure. We also expected to find that rhodanine would inhibit the virus-induced shutoff of host cell protein synthesis. Indeed, our experiment showed that no host shutoff takes place in echovirus 12-infected cells in the presence of rhodanine, whereas in the untreated

control host cell protein synthesis is repressed to less than 20% of the mock-infected control by 3 h p.i. (Fig. 1).

In contrast the shutoff induced by poliovirus 2 (strain P 712-ch-2ab) was not affected by rhodanine (Fig. 1). That is consistent with the fact that the multiplication of poliovirus 2, unlike that of echovirus 12, is unaffected by rhodanine^{12,13}.

Fig. 1 Confluent monolayers of GMK cells were infected with echovirus 12 (20-50 plaque-forming-units (PFU per cell) or poliovirus 2 (50-100 PFU per cell) in the absence or presence of 100 $\mu\text{g ml}^{-1}$ rhodanine. Rate of protein synthesis was measured as follows: L-(4, 5-³H)-leucine was added to an aliquot of the cells at various times p.i. The cells were collected 30 min later, and the radioactivity incorporated into trichloroacetic acid precipitable material was determined. Broken lines denote presence of rhodanine, solid lines denote absence of rhodanine. $\times$, Mock infection; $\circ$, echovirus 12 infection; Δ , poliovirus 2 infection.

The shutoff effect by echovirus 12 is, within experimental limits, as dependent on the multiplicity of infection as it is with poliovirus 2 (Fig. 1). We do not know whether the effects of rhodanine would persist at still higher multiplicities. This experiment might be complicated by emergence of rhodanine-resistant or -dependent mutants¹².

This result demonstrates that the specific inhibitor of uncoating of echovirus 12, rhodanine, also prevents the virus-induced shutoff of host protein synthesis. Obviously, adsorption and penetration are not sufficient to induce the effect; uncoating is a necessary prerequisite for this shutoff to occur. The virion per se—for example, by depressing some cellular function(s)—is not able to induce host cell shutoff.

Rhodanine thus seems to fulfil some of the ideals

clinicians ask for in viral chemotherapies—it affects an early stage of virus-cell interaction leaving intact vital functions of the cell.

Guanosine tetra- and pentaphosphate synthesis by bacterial stringent factor and eukaryotic ribosomes

AMINO acid starvation of *rel*⁺ bacteria¹ results in a rapid pleiotropic response involving the cessation of stable RNA synthesis, a decrease in the rate of nucleoside transport, an altered pattern of mRNA synthesis, inhibition of phospholipid synthesis and increased protein turnover. This stringent response² is rapidly reversed when the amino acid starvation is relieved and is apparently mediated by two unusual nucleotides, guanosine 5'-diphosphate, 3'-diphosphate (ppGpp) and guanosine 5'-triphosphate, 3'-diphosphate (pppGpp)³. These nucleotides are synthesised on the ribosome in the presence of uncharged tRNA, ATP, GTP and an enzyme known as stringent factor³. Mutants which fail to exhibit the stringent response to amino acid starvation with the synthesis of ppGpp pppGpp are known as relaxed mutants⁴ and in *Escherichia coli* are mapped at three loci; *relA* (ref. 5), *relB* (ref. 6), and *rplK* (*relC*) (refs 7 and 8). The synthesis of ppGpp and pppGpp has also been observed in various prokaryotes including blue-green algae⁹. Here we demonstrate the ability of bacterial stringent factor to be stimulated by eukaryotic ribosomal preparations to synthesise both ppGpp and pppGpp.

In eukaryotic cells, viral transformation results in the loss of regulation of many macromolecular processes involved in the response of resting cells to serum deprivation¹⁰. This loss in regulation is reminiscent of that observed in relaxed bacteria. Hershko *et al.*¹⁰ suggested that normal fibroblasts and virally transformed fibroblasts were analogous to stringent and relaxed bacteria respectively. Attempts to find ppGpp and pppGpp in eukaryotic cells have been generally unsuccessful^{11–13}, however, although in the last 2 yr a number of reports describing the accumulation of these compounds have been published, both *in vivo*^{14,15} and in ribosome dependent reactions *in vitro*^{16,17}.

Our inability to duplicate the synthesis of ppGpp in CHO cells as reported by Rhaese¹⁵ and failure to detect ppGpp and pppGpp in a temperature sensitive (*ts*) leucyl-tRNA synthetase mutant of CHO cells at either permissive or non-permissive temperatures¹³, led us to examine the *in vitro* ribosome-dependent reaction reported by Irr *et al.*¹⁷. In this reaction there might be less chance of a rapid degradation of any ppGpp or pppGpp synthesised. Preliminary attempts to duplicate the work of Irr *et al.*¹⁷ using 11- and 14-d-old mouse embryo ribosomes were unsuccessful (Table 1), using either the ribosome assay described by Irr *et al.*¹⁷ or the assay described by Haseltine and Block¹⁸. Addition of purified stringent factor¹⁹ from *E. coli*, how-

ever, resulted in the synthesis of ppGpp and pppGpp (identified by the co-migration with authentic bacterial ppGpp and pppGpp) converting up to 80% of the GTP over a 2-h incubation period into these guanosine nucleotides (Fig. 1, Table 1). The synthetic reaction observed was slightly different from that seen for *E. coli* ribosomes in that the preparations of eukaryotic ribosomes were rapidly able to convert GTP to GDP, which is used in the synthesis of ppGpp (Fig. 1). Synthesis of ppGpp and pppGpp was dependent on ribosomes, GTP, ATP and stringent factor, omission of any one produces less than 0.1% conversion of the added GTP (Fig. 1). Ribosome preparations were not purposely depleted of bound tRNA and mRNA¹⁸, because we desired to keep the mammalian system as intact as

Table 1 Ability of eukaryote ribosomes to synthesise guanosine penta- and tetraphosphate in an *in vitro* ribosome assay

Ribosome source	µg RNA per assay	Reaction time (h)	% of GTP converted to ppGpp and pppGpp	
			Stringent factor	
			40 µg ml ⁻¹	0 µg ml ⁻¹
<i>E. coli</i> salt washed	9.3	2	92.7	<0.1
11-d mouse embryo	1	2	1.1	<0.1
	2	2	44.0	<0.1
	3	3	61.0	<0.1
14-d mouse embryo	1	2	81.3	<0.1
	2	2	18.0	<0.1

Assays were performed as described in Fig. 1. Ribosomes were prepared by the method of Irr *et al.*¹⁷, except the ethanol precipitation step was omitted in all preparations other than the first 11-d mouse embryo experiment. Ribosomal integrity was confirmed by linear (10–40% w/w) sucrose gradient sedimentation analysis²⁰.

possible. Therefore, dependency on these factors was not tested although they were routinely added to the assay.

Lack of a putative stringent factor activity in eukaryotic ribosomes could be accounted for by its lability during the purification procedure for ribosomes described by Irr *et al.*¹⁷. Therefore, ribosomes with various degrees of purity and prepared in other manners were also tested in the *in vitro* assay. We also tested ribosomes prepared from several other eukaryotes. In no case was a stringent factor independent reaction observed, although ribosomes from all sources tested could be stimulated to synthesise ppGpp and pppGpp upon the addition of stringent factor from *E. coli* (Tables 1 and 2). This test also included ribosomes from a *ts* mutant of leucyl-tRNA synthetase in CHO cells²⁰ (Table 1) supporting the *in vivo* data indicating the lack of synthesis of ppGpp and pppGpp in this cell line¹³. The extent of reaction was rather variable (Tables 1 and 2) because ribosomes were not prepared to maintain maximal function but rather by a variety of methodologies in the hope of achieving the independent synthesis of ppGpp and pppGpp by eukaryotes. Therefore quantitative comparisons between groups cannot be made.

Mitochondria from rat liver have been reported to synthesise ppGpp and pppGpp upon the addition of bacterial stringent factor¹⁶. In the present experiments, however, we believe that mitochondrial ribosomes could not be responsible for more than a small percentage of the activity for the following reasons; (1) ribosomes were routinely prepared under conditions where all mitochondria should have been removed, (2) ribosomal preparations showed no 70S peak (<1%) on sucrose gradients even when large quantities of ribosomes were layered on to gradients for preparative purposes.

It is quite possible that the reaction we observed is relatively nonspecific. Crude preparations of *E. coli* stringent factor in the absence of ribosomes can be stimulated to synthesise ppGpp and pppGpp by 20% methanol²¹, although not under the assay conditions employed here (J. Parker, unpublished). Christiansen and Nierhaus²² have shown stimulation of ppGpp and pppGpp synthesis by stringent factor with a variety of *E. coli* ribosomal proteins.

It may be pertinent to point out that immunological cross-reactivity occurs between chicken liver and *E. coli* ribosomal proteins L7 and L12 (ref. 23).

Richter¹² reported that yeast, reticulocyte and calf brain ribosomes were not stimulated by *E. coli* stringent factor. Beres and Lucas-Lenard²⁴ could not stimulate Ehrlich ascites cell ribosomes, but could stimulate wheat germ ribosome with *E. coli* stringent factor. But, as we show here, ribosomes from various sources were stimulated by *E. coli* stringent factor although some of the yeast preparations were inactive. Although the reasons for these discrepancies are not clear, the stringent factor routinely used in the present report was greater than 50% pure whereas in both other reports relatively crude preparations were used. In our hands even a crude preparation of stringent factor could stimulate eukaryotic ribosomes to

Fig. 1 *In vitro* synthesis of ppGpp and pppGpp by 14-d-old mouse embryo ribosomes and *E. coli* ribosomes in the presence of bacterial stringent factor. *a*, Time course of synthesis of ppGpp and pppGpp. Assays were performed as those of Haseltine and Block¹⁸. 14-d mouse embryo ribosomes were present at a final concentration of 10.4 μg per 50 μl (○), 24 μg per 50 μl (Δ) and *E. coli* ribosomes at a final concentration of 9.3 μg per 50 μl (x). Two μg per 50 μl of at least 50% pure *E. coli* stringent factor (Pedersen and Parker, unpublished) was added where indicated and the reaction mixtures incubated at 37 °C for varying times. The assay lacking ribosomes (●) or lacking *E. coli* stringent factor (▽) gave no detectable synthesis of ppGpp or pppGpp (<0.1% of α -³²P-GTP (Amersham Radiochemicals, specific activity >1 μCi μmol^{-1}) present at 27.5 nmol per 50 μl assay). *b*, A characteristic polyethylene-imine cellulose chromatogram¹⁸ (Brinkman Instruments) of the reaction products of the assay described in (*a*). *E. coli* ribosomes were present at a final concentration of 9.3 μg per 50 μl and 14-d mouse embryo ribosomes at a final concentration of 26.0 μg per 50 μl . Reaction mixtures were incubated at 37 °C for 2 h.

Yeast	+	—
Rat liver§	+	—

Assays were performed as described in Fig. 1. Stringent factor was present at 40 $\mu\text{g ml}^{-1}$, except with exogenous *E. coli* ribosomes, where no stringent factor was added. Omission of stringent factor gave no detectable spots of ppGpp or pppGpp or autoradiograms and no counts above background (—). The sensitivity of the assay would have detected 27.5 pmol of ppGpp or pppGpp. Positive results (+) ranged from three times background (rat liver) to three hundred and fifty times background (yeast). Ribosomes from tetrahymena, yeast and rat liver were kindly provided by Mr Peter Ganz, Dr W. Galen McKeever and Dr Doris M. Nicholls, York University, Toronto, respectively.

*Ribosomes were prepared by the method of Irr *et al.*¹⁷

†Cells homogenised as described by Stanners and Thompson¹³ and nuclei removed by centrifugation twice at 650g for 3.5 min and mitochondria once at 7,000g for 10 min. A microsomal fraction was obtained by centrifugation for 1.5 h at 105,000g. Pellets were resuspended in buffer C (0.05 M Tris-acetate pH 8.0 at 10 °C, 0.015 M magnesium acetate, 0.06 M potassium acetate, 0.27 M ammonium acetate, 0.001 M EDTA, 0.0001 M dithiothreitol) and frozen at –70 °C until used.

‡Cell supernatants prepared as described by Stanners and Becker²⁹ were layered over 34 ml linear sucrose gradients (15–30% w/w) in 0.01 M Tris-HCl pH 7.4 at 20 °C, 0.1 M NaCl, 0.02 M MgCl₂ and centrifuged for 2.5 h at 27,000 r.p.m. in a SW27 rotor at 4 °C. The monosome and polysome fractions were collected in a LKB fraction collector after monitoring absorbance at 260 nm. Purified ribosomes were concentrated by centrifugation for 14 h in a SW41 rotor at 41,000 r.p.m., resuspended in buffer C and frozen at –70 °C until used.

§The rat liver ribosome preparation converted 91% of the added α -³²P-GTP c.p.m. to inorganic ³²P-phosphate during the course of the reaction.

synthesise ppGpp and pppGpp (unpublished observations).

In conclusion, we find eukaryotic ribosomes are unable to synthesise guanosine penta- and tetraphosphate *in vitro* except in the presence of bacterial stringent factor. Although several methods of ribosome preparation were used to attempt to maintain the activity of a postulated eukaryotic stringent factor no stringent factor activity was found. We cannot, however, rule out the possibility that such a factor exists but is extremely labile. The majority of the *in vivo* experiments^{11–13, 25–28} and our unpublished results argue against this possibility. In light of the present experiments, previous positive results in *in vivo* eukaryotic experiments may well have resulted from prokaryotic contamination of animal cells.

We thank Drs J. Friesen and C. P. Stanners for help and advice, and Dr M. Pearson for critically reading the manuscript. The work was supported by the MRC, NCI and NRC of Canada. J. W. P. is a Research Fellow of the National Cancer Institute of Canada.

Quenching of chlorophyll fluorescence by β -carotene

CAROTENOID pigments are closely associated with chlorophyll molecules in the chloroplast structure^{1,2}. Some carotenoids, for example fucoxanthol³, can act as efficient sensitizers for the formation of the excited singlet state of chlorophyll although others, such as β -carotene, are very inefficient^{2,4,5}. Other functions of carotenoids include acting as a deactivator of triplet chlorophyll (and hence protect the chlorophyll from photodegradation and also intercept the production of singlet oxygen) and as a deactivator of singlet oxygen⁶. Here we report *in vitro* experiments which unequivocally demonstrate that β -carotene quenches the excited singlet state of chlorophyll.

A previous report of the quenching of chlorophyll fluorescence by β -carotene⁷ has been shown to be in error^{8,9}. From a simple consideration of the Stern–Volmer quenching kinetics it can be shown that to measurably quench the chlorophyll *a* excited singlet state of lifetime in benzene 5.73 ns, a quencher concentration of $>10^{-3}$ M is required and thus a report¹⁰ of observed quenching of chlorophyll fluorescence by β -carotene at a concentration of 1×10^{-5} M also seems to be in error.

Steady state, quantitative measurements of the quenching of chlorophyll fluorescence by β -carotene are complicated by the fact that the absorption spectra of the two compounds overlap at wavelengths appropriate for excitation of the chlorophyll and also there is overlap of the β -carotene absorption band with the chlorophyll fluorescence. It is therefore necessary to make extensive corrections to the observed fluorescence intensities. The reported results are based on measurements made with 1 cm² cells and cylindrical cells with an internal diameter of 0.2 cm.

Chlorophyll *a* was used as soon as possible after extraction from *Poa annua* and its purity checked by comparing the relative intensities of its absorption bands at 410, 430, and 662 nm with those in the literature¹¹. For some measurements, chlorophyll *a* from Sigma Chemicals was used: spectral properties of the extracted and commercial samples were identical. Synthetic all *trans* β -carotene (Sigma) was used and its purity checked by measuring the extinction coefficient of its absorption band at 450 nm. The shape of the absorption curve matched, in details, with the literature spectrum for the compound¹¹. The absorption

spectrum of the β -carotene used in the experiments was independent of the concentration used. For all the concentrations used there was no apparent deviation from Beer's law. The linearity of the Stern–Volmer is a further indication that β -carotene does not aggregate at the concentrations employed. Spectrograde benzene (BDH and Merck Uvasol) was used as solvent. For measurements in the square cells, the chlorophyll solution had an optical density of 0.39 at the excitation wavelength (662 nm). The fluorescence intensity was measured at 670 nm. In all cases the solutions were air-saturated. The results of using the square and cylindrical cells are shown in Fig. 1. The agreement between the two sets of results is not very good but the values show that the quenching process has a rate constant of $\sim 5 \times 10^9$ M⁻¹ s⁻¹ which is close to the diffusion controlled limit of 1×10^{10} M⁻¹ s⁻¹ (ref. 13).

To check the steady state quenching data, measurements were made of the quenching effect of β -carotene on the lifetime of the excited singlet state of chlorophyll *a*. Fluorescence lifetimes were measured using time correlated single photon counting¹⁴. The solutions were excited at 550 nm and the emission at 670 nm monitored with a Phillips 56 TUVP photomultiplier tube. The fluorescence was observed at the back of a 1 mm path length cell. In all cases the fluorescence decays were exponential. The results are shown in Fig. 1. The rate constant for quenching, 4.5×10^9 M⁻¹ agrees well with the steady state measurements.

A surprising observation was that the admixing of β -carotene and chlorophyll *a* in aerated solution gave rise to chemiluminescence. The emitting species (as shown by its spectrum) is the excited singlet state of chlorophyll. This luminescence may arise as a result of the thermal dissociation of a β -carotene oxidation product (perhaps a 1,2-dioxetane) to give products in their excited singlet state. Förster-type energy transfer from these excited molecules to β -carotene should occur and ultimately some of the energy be trapped by the chlorophyll lower excited singlet state from which fluorescence occurs.

Since the energy of the excited singlet state of chlorophyll lies below that of β -carotene, the quenching of chlorophyll fluorescence cannot be attributed to an energy transfer process. From the fact that polyenes such as β -carotene have low ionisation potentials and are known to act as electron donors towards excited singlet states¹⁵, we propose that the quenching occurs via an electron transfer process,

The initially produced intermediate may be a non-emissive exciplex. If the quenching occurs in a polar environment radical ions should be produced. Whether or not these can be used in the photosynthetic process is dependent on a number of factors. Of particular importance is the likelihood of back electron transfer before the ions have diffused out of the solvent cage in which they were generated. This type of reaction readily occurs when the radical ions are generated from excited singlet states^{16,17}. We have proposed a similar mechanism to account for the quenching of methylene blue fluorescence by β -carotene¹⁸. Since there is only a little evidence¹⁹ for chlorophyll *a* acting as an electron acceptor in its singlet state we studied the quenching of its fluorescence by other donors, *N,N*-dimethylaniline, indole and skatole. The quenching rate constants for the compounds in methanol solution were found to be 3.4, 0.3 and 0.3×10^8 M⁻¹ s⁻¹ respectively and for indole in benzene solution a value of 3×10^8 M⁻¹ s⁻¹ was obtained.

At first sight, the reported result is in direct conflict with the many well established results on the *in vitro*²⁰ and *in vivo*^{21,22} sensitisation of chlorophyll fluorescence by carotenoids. Because many carotenoids exhibit only very weak fluorescence in solution, energy transfer was demonstrated by an indirect method—the excitation spectrum of the fluorescence of chlorophyll *a* in a chlorophyll– β -carotene mixture was shown to contain bands due to β -carotene²⁴. These experiments cannot,

Fig. 1 Quenching of the fluorescence, and fluorescence lifetimes of chlorophyll *a* by β -carotene. Δ , τ_0/τ (— best fit K_{SV} 22.5); $\bullet$, Φ_{F0}/Φ_F (square cells, — best fit K_{SV} 26 $\pm$ 5); $\blacksquare$, Φ_{F0}/Φ_F (cylindrical cuvette — — — best fit K_{SV} 37 $\pm$ 5). τ and τ_0 , Chlorophyll *a* lifetime in presence and absence of β -carotene. Φ_F and Φ_{F0} , Chlorophyll *a* fluorescence quantum yields in presence and absence of β -carotene. $[Q]$, Quencher concentration; K_{SV} , Stern-Volmer quenching constant. Φ_{F0}/Φ_F was calculated by the following procedure: consider the fluorescence from the centre O of a cell, illuminated at X by light of intensity I , and observed at right angles at Y.

In the absence of a quencher let the transmittance of the solution over XO and OY be x and y respectively. Then the fluorescence intensity at Y, $F_0 = Ixy\Phi_{F0}$. If the transmittance of a solution of pure quencher over XO and OY is α and β respectively, then the new observed fluorescence intensity of quenched chlorophyll solution, $F_{obs} = Ixy\alpha\beta\Phi_F$. Hence the observed Stern-Volmer quenching $F_0/F_{obs} = \Phi_{F0}/\alpha\beta\Phi_F$. $\alpha = 10^{-\epsilon_1 c l}$ and $\beta = 10^{-\epsilon_2 c l}$; ϵ_1, ϵ_2 are extinction coefficients of β -carotene at excitation and monitored emission wavelength respectively; c is quencher concentration; l is distance from centre of cuvette to X and Y (normally equal).

because of their design, show whether the quenching process occurs.

We propose that the role of carotenoids in photosynthesis is wider than originally envisaged. On interaction of the excited singlet state of β -carotene with chlorophyll the energy can be partitioned between energy transfer and an electron transfer process. The relative importance of the two processes will be determined by the orientation and the distance separating the two molecules. Since energy transfer occurs by a resonance process²⁰⁻²², it should be favoured relative to the redox process by an increase in the distance separating the two molecules. The environment of carotenoids in the antennae is known to be different from that in the reaction centre^{24,25}. In the antennae resonance transfer from carotene to chlorophyll and rapid resonance transfer from one chlorophyll molecule to another may compete successfully against the electron transfer reaction such that only resonance transfer is occurring. At the reaction

centre, resonance energy transfer from the centre to a chlorophyll molecule outside the centre becomes inefficient because of the lower energy of the excited singlet state of the chlorophyll in the centres. Consequently, the electron transfer should be favoured and a chlorophyll radical anion and a carotene radical cation formed. This latter species will undergo a rapid ground state reaction with a neighbouring chlorophyll molecule^{22,26} to generate a chlorophyll radical cation²⁷ and thus the overall effect of the electron transfer reaction is to produce a charge separated pair Chl^-Chl^+ . It has been proposed that such a dimer species is involved in photosystem II (ref. 25).

Corrigendum

In the article 'Economics of alternative energy sources' by Martin Ryle, *Nature* **267**, 111-117, the figures given in Table 1 under Present Gas Turbine Generators should have included two entries: *a*, the contribution from oil-fired steam stations, showing an annual variation and *b*, the contribution from gas turbines used for peak boosting. These figures were inadvertently combined and used with the gas turbine time variations. The correct figures lead to a reduction in the final peak value in the Table from 187 to 163 GW and a reduction in the installed capacity needed from 266 to 233 GW; these figures are still some 50 times those of the present nuclear capacity.

matters arising

Culture and genetic variability

CHAKRABORTY found¹, by using gene frequencies for seven serological markers to compute genetic distance, that 'only geographical distance seems to be important, explaining the trend in genetic variabilities' in seven Chilean Indian populations. The correlation coefficients he presented were 0.716, 0.775, and 0.901, for correlations between genetic distance-geographical distance, genetic distance-cultural dissimilarity, and geographical distance-cultural dissimilarity, respectively. He then presented the results from a stepwise regression, and found that while geographical distance explained 51.31% of the genetic variation, cultural dissimilarity explained only an additional 8.88%. He did not, however, use as the first variable in the stepwise regression the one which had the highest correlation with the dependent variable. Culture alone accounts for 60.06% (r^2) of the genetic variation in these data. If geographical distance is then added, the additional variation explained would be less than 0.2%. These figures are, of course, approximations subject to slight rounding error from the published tables. It is indeed difficult to assess the relative importance of variables which are themselves highly correlated, as Chakraborty states. But his data clearly do not support his conclusion that of the variables measured, only geographical distance is an important correlate of genetic distance. From these data, culture is at least of equal importance.

It would be profitable to use these data to consider the relative effects of genetic and geographical distance upon culture. Geographical distance apparently explains 81.18% of cultural diversity as measured in this study. This leaves a smaller, but possibly significant, proportion of cultural variation which might be explained by the genetic measure.

PENELOPE J. GREENE

*Population and Developmental Biology Group,
School of Biological Sciences,
University of Sussex,
Brighton, Sussex, UK*

CHAKRABORTY REPLIES—Greene¹ contests my assertion regarding the relative importance of geographical versus cultural separation as a correlate of genetic variation in seven Chilean populations². In so doing, she notes that in the stepwise regression procedure I used geographic distance as the first variable even when the cultural dissimilarity index had a higher product moment correlation with genetic distance (the dependent variable). Two reasons justify my choice of geography as the first independent variable to be entered in the regression analysis, one being theoretical, the other pragmatic.

Take, for instance, cultural variability as the dependent variable. Evaluation of the relative effects of geographical and genetic distances on cultural variability indicate that 82.41% of the cultural variability is explained by geographical distance ($P < 0.0005$), whereas the additional effect of genetic distance is 4.01%, which is statistically insignificant ($0.10 > P > 0.05$). This alone may suggest that geographical distance should be the first variable of interest.

The pragmatic view concerns the choice of the characteristics determining cultural diversity. As elaborated elsewhere³, it is difficult to ascertain that cultural attributes are independent of geography. For example, we classified the seven populations on the basis of their types of subsistence, housing and architecture, economics, mode of gathering food, etc., which do have strong geographic components embedded in them. Thus, the strong association between cultural affinity and geographic proximity is indeed historical in these seven populations.

Furthermore, a stepwise regression method often under-represents the importance of the last variable to go in, particularly when the independent variables are significantly correlated with the dependent one. A logical explanation of causal relationship in such an event has to be based on an understanding of the process producing the covariation between the variables, and not based on which independent variable has the highest correlation with the dependent one.

Greene's criticism, therefore, should be viewed with caution, although any generality of my analysis needs further examination, possibly from studies of

other populations with comparable ethnographic accounts.

Do viruses use calcium ions to shut off host cell functions?

IN discussing the shut-off of host cell functions by poliovirus, Carrasco and Smith¹ ask: "How does a viral protein change the ionic environment inside the cell?" Perhaps it forms channels across the external membrane². For example, a viral structural protein might generate holes by assembling into hexamers, pentamers, or extended lattices in a membrane.

Although Carrasco and Smith emphasised Na^+ ions, divalent ions are probably more important controllers of metabolism. In general, Ca^{2+} , Mg^{2+} and polyamine ions tend to form much more specific links with polyelectrolytes than Na^+ or K^+ do³, and the Debye-Hückel concept of ionic strength grossly underestimates the relative binding of, say, Ca^{2+} compared with K^+ , to membranes and viruses⁴. Many enzymic activities depend upon divalent ions, while relatively few respond to physiological changes in monovalent ion concentrations.

Of the two main divalent ions in biology, it is Ca^{2+} , not Mg^{2+} , that usually acts as a signal. This is because Ca^{2+} is actively pumped to at least a thousandfold concentration difference across membranes⁵, whereas Mg^{2+} is much nearer equilibrium⁶, probably because it permeates more easily. The fact that cells respond more to changes in extracellular Mg^{2+} than Ca^{2+} has misled some workers into putting a false emphasis upon the ions' relative roles⁷.

The early effects of many lytic viruses can readily be interpreted as a consequence of increased flow of Ca^{2+} into

¹ Chakraborty, R. *Nature* 264, 350-352 (1976).

cells. In some cases structural components of the virus perhaps act as the ionophores^{1,8,9}, while in others new proteins may need to be synthesised. The many phenomena observed in practice would then be merely the different facets of a fundamental gear-shift in polyelectrolyte-counterion interactions within the cell.

CARRASCO AND SMITH REPLY—We find the proposal by Durham that changes in calcium ion concentration following infection by viruses are responsible for alterations in host cell functions very attractive. Our model to explain the shut-off of protein synthesis, which was briefly summarised in our *Nature* paper¹, and which is the subject of a more detailed paper², is in fact very similar. We also favour a model in which viral structural proteins form lattices in the cellular membrane and leave holes which act in the same way as some ionophores to allow the passage of ions².

We believe, however, that the shut-off of host cell protein synthesis is best explained by a change in Na⁺ ion concentration within infected cells, and we presented experimental evidence showing that sodium ions can have a differential effect on protein synthesis *in vitro* and indirect evidence that such changes in sodium ion concentration could occur *in vivo*¹. While we have not examined the effects of calcium ions in detail, a preliminary screening of the effects of many mono- and divalent cations on protein synthesis *in vivo* and *in vitro* failed to reveal a differential effect by calcium ions.

Sodium emission in persistent meteor trains

USING theoretical estimates of the rate coefficient of the association of Na with O₂, Kolb and Elgin¹ have shown that the catalytic effect of sodium in releasing the store of recombination energy of free atmospheric atomic oxygen is more powerful than was previously assumed². Drawing on evidence from measured Na D-line intensities, Kolb and Elgin estimate a branching ratio for the production of excited Na(²P) from NaO reduction of $f \sim 0.05$, which, using the model previously suggested² implies that at 90 km sufficient photon emission occurs for an enduring train to result from a meteor of magnitude about –6. It is instructive to relate this estimate to observation. It is known that the trains of small duration show an initial emission decay at 90 km of about³ 0.2 mag s^{–1} and since the radiation probably results from the interaction of ionic constituents of the train so that the reaction rate varies inversely as the meteor column cross-sectional area and hence inversely as time, a decay of 5 mag would be expected between about 1 s and 100 s. We may infer that any train luminosity having a duration $t \gtrsim 100$ s must be due to a catalytic (sodium) mechanism. In Olivier's catalogue⁴ 55% of trains ($t > 10$ s) were produced by high velocity shower meteors, Perseids, Orionids and Leonids. In the duration-magnitude characteristics given for 3700 trains by Millman⁵ the average meteor magnitude corresponding to a duration of 100 s is in the range –7.5 to –5 for velocities 60–70 km s^{–1}. From the extensive surveys of Hoffmeister (see ref. 4) and Olivier, one visual meteor in 780 results in a train of duration $t > 10$ s. Using ref. 5 the difference in magnitudes between meteors responsible for trains of 10 s and 100 s duration is 2.5 implying a corresponding incident meteor flux ratio⁶ of 27:1. Since the mean visual meteor rate⁶ to a single observer is 9.7 h^{–1} the observed occurrence frequency of trains $t > 100$ s is 4.6×10^{-4} h^{–1}. In comparison the cumulative flux of meteors having magnitudes brighter than –6 for an individual observer is, using Hughes⁷ 3.1×10^{-4} h^{–1}. Though there are uncertainties in [O₂] and f and variations in Na abundance, the sodium cycle process is strongly supported as a source of persistent meteor train luminosity. This conclusion may be viewed in the light of the review of train characteristics by Hughes⁷.

Hughes considered evidence for the mechanisms responsible for persistent meteor train emission and on the basis of visual observations^{8,9} concluded that

the evidence supported a mechanism that is closely associated with the level of meteoric ionization rather than with meteoroid mass or meteor luminosity. It is of importance to emphasise that based on the observations^{8,9} the conclusion of Hughes is inappropriate. The results of Lindblad⁸ for Perseid meteor trains are confined to very short durations, t : for only 2% of the trains was $t > 3$ s while for 90% $t < 1.5$ s indicating that the observed light was associated with the meteor wake emission and in particular the well known OI 5577 Å feature. Indeed the data of Lindblad permit the determination of the effective lifetime τ (decay constant) of the emitting species. It is straightforward to show that the gradient of train duration-meteor magnitude plot is given by $-\tau(\log_{10})/1.51$ and using Lindblad (Fig. 11B) $\tau = 0.21 \pm 0.05$ s. In comparison, the radiative lifetime of the OI (¹D₂ ← ¹S₀) transition is 0.74 s. However the great majority of observed trains were in the 90–100 km height interval (Lindblad, Fig. 18) where deactivation of the O(¹S₀) state most effectively occurs with O and O₂. Using recommended quenching coefficients and known atmospheric concentrations the quenching rate at 95 km is ~ 2.9 s^{–1} resulting in an effective emission lifetime of 0.23 s. Plavec⁹ does not state the durations of trains in his analysis. We note, however, that according to Plavec (a), the trains disappeared in a few seconds, (b), there was concern with the effects of observer reaction times on duration measurements (c), 50% of Perseid meteors yielded trains in contrast to the much lower proportion at lower meteor velocities. The results indeed coincide with what is now known about the green line emission (the 5,577 Å feature was not identified until 1958). It is quite clear that the observations of Lindblad and Plavec do not refer to the true rare enduring train phenomenon.

reviews

Thinking about complexity

Eric Ashby

Tools for Thought. By C. H. Waddington. Pp. 250. (Jonathan Cape: London, 1977.) £5.95.

HAL WADDINGTON did not live to see this book through the press. It is a fitting valedictory from one of the few of my contemporaries who deserve the epithet 'Renaissance Man'. Thirty-six years ago he published a little book called *The Scientific Attitude*, which delighted us by weaving poetry and art (with illustrations from Auden, Spender, Picasso and Paul Klee, among others) into a fabric of closely knit rational argument about science. For a generation he continued to carry out distinguished research in biology, and at the same time to publish thoughtful and stimulating work on ethical and social issues. In February 1975 he presided over an imaginative symposium at the Ciba Foundation, on *The Future as an Academic Discipline*. Over morning coffee he showed me the rough drafts of two books which were to embody his recent thinking. One draft was on *Man-Made Futures* (alas, not sufficiently advanced to be published posthumously); the other draft was *Tools for Thought*.

The title of the book accurately describes its content. Open your newspaper any morning and you'll read items such as these: conflict over transport policy for London; industrial dispute over the introduction of new equipment for typesetting; threat of a strike among sewage workers; apprehension about aerosols and ozone, or saccharine and cancer; alarm about population growth; warnings about depletion of resources; diplomatic hassles in the Middle East. We suffer saturation bombardment with advice about these issues, panaceas, utopian scenarios. What we rarely get is help on how to think about them. Waddington's book offers this help.

All these issues, and scores of others like them, have one property in common: they are embedded in a network of complexity. If doing *a* simply caused *b*, which in turn simply caused *c*, with no side-effects, how simple these issues would be to understand! But the tool

of linear thinking is useless on problems of complexity. It is well known that there are now new tools for thought—labelled systems analysis, information theory, decision theory, cybernetics, and so on. But most people who have not had to use these tools for professional purposes know very little about them and are put off by the turgid jargon in which they are packaged.

The purpose of Waddington's book is to provide a plain man's guide to these new tools for thought. It's not an instruction manual to teach you how to use them, but it demonstrates their capacities and their limitations, and it provides enough concrete examples to convince the plain man that what Waddington calls "Conventional Wisdom of the Dominant Group" (with the felicitous acronym COWDUNG) is often totally inadequate to handle contemporary social and technological problems.

After an introduction which identifies Waddington as a neo-Whiteheadian the book describes the conceptual tools for thinking about complex systems. First, it deals with shapes, with an illuminating digression on hierarchies and the use of matrices and Venn diagrams. It then deals with processes: a lucid exposition of exponentials and their consequences, sigmoid curves, feedback, chain reactions, the unexpected phenomena like schismogenesis discovered by Gregory Bateson, and an inkling of the way topologists describe complex social interactions by the use of catastrophe theory. After processes come communications, with a summary of some of the astonishing consequences of programming patterns into a computer. Communication leads to games theory and operational research, and this in turn to technological forecasting and system modelling (the one section of the book which I'm sure Waddington would have wished to revise if he had had the opportunity).

This is a catalogue of techniques daunting enough to repel the plain man for whom it is written. But my guess is that the plainest of men will find the book hard to put down. One of its delights is that it is so easy to read and

yet Waddington hasn't fudged any of the intellectual difficulties. The style is informal, conversational, as if the book had been taped direct from lectures. It combines a rare gift for popularisation with uncompromising scientific integrity; several times in the book Waddington as good as says: "I've shown you how this tool is used, but don't imagine you now know how to use it yourself. You don't." Just as the reader may be becoming puzzled at the description of some concept, Waddington throws in a specific example which dispels the puzzlement. Thus, in discussing the "prisoner's dilemma" (that theme so dear to philosophers and so ludicrous to the plain man), Waddington suddenly says that this is the paradigm for discussion about urban transport (I'll give up my car if everyone else gives up his car), grazing rights (I'll run fewer cows on the common if the others do the same), and the East-West arms race.

The book is illustrated by diagrams, most of which are deliberately imprecise because, as Waddington writes in the introduction, they are there to illustrate ideas, not facts. I see his point but I'm not happy about these diagrams. They are the sort of crude sketches you'd make on the blackboard while talking to a class. Some of them are insufficiently explained in the text. I may be pernickety, but in an otherwise elegantly printed book, I would like the lines marking the ordinates and abscissae of graphs to be straight. Graphs can be informal, but nevertheless tidy (as they are, for instance, in Hogben's *Mathematics for the Million*).

Hal Waddington was not able to correct the proofs of this book. Whoever did correct them ought to have taken more care. There are several misprints, some of them serious (for example, the date of Waddington's Bernal Lecture on p237). The diagram on p99 is upside down. I believe a diagram is missing altogether on p202, and possibly also on p220 or p221. The figure on p214 is inconsistent with the text. An *n* is missing from the equation on p207. Many of the diagrams could

be improved not only by a judicious use of a ruler to draw straight lines but by the addition of legends to supplement references in the text.

The book is, in my view, a brilliant essay for the plain man, particularly for the plain politician and administrator, who wants to understand how experts study complexity. It is a generous bequest from one of the most distinguished biologists of his generation. It deserves to be re-issued for a

wider public as a paperback at a moderate price; but it would be a courtesy to the memory of Hal Waddington to re-edit the book conscientiously before it is re-issued. □

Lord Ashby was formerly Master of Clare College, Cambridge. He is Chancellor of the Queen's University, Belfast, and is at present Walgreen Professor of Human Understanding at the University of Michigan.

Mathematical treasure

Proofs and Refutations: The Logic of Mathematical Discovery. By Imre Lakatos. Edited by John Worrall and Elie Zahar. Pp. xii+174. (Cambridge University: Cambridge, London and New York, 1976.) Hardcover £7.50; paperback £1.95.

For anyone interested in mathematics who has not encountered the work of the late Imre Lakatos before, this book is a treasure; and those who know well the famous dialogue, first published in 1963-64 in the *British Journal for the Philosophy of Science*, that forms the greater part of the book, will be eager to read the supplementary material. The dialogue is what Lakatos calls a "rational reconstruction of history", that is, the history of the Euler conjecture on polyhedra ($V-E+F=2$); the purpose is to illustrate principles of methodology. The participants seem themselves to be more interested in methodological questions than in the mathematical problem, which imparts a somewhat ponderous tone to the discussion; but the reconstruction, and the actual historical information given in the extensive footnotes, are in themselves fascinating. The supplementary matter, extracted by the editors of this posthumous work from earlier unpublished writings by Lakatos, and not revised by him before his death, consists, first, of a conclusion to the dialogue, in the form of a discussion of Poincaré's proof, and, secondly, of much briefer case studies, not in dialogue form, of examples from analysis and measure theory.

The original dialogue, without this supplementary material, was stimulating but tantalising, in that it was unintended his readers to draw. Plainly, clear just what conclusions Lakatos one is a methodological thesis, concerning the process of mathematical discovery. According to Lakatos, the best model for this process is not the linear, Euclidean one of indubitable deductions from an initial set of axioms and

definitions, but that of an interplay between ideas for proofs and counter-examples in the light of which the proof is progressively improved. We begin, typically, with a conjecture and a tentative proof. We should then seek for counter-examples, guided by the proof: when these are found, we should not rule them out by *ad hoc* ("monster-barring") definitions, even when it can plausibly be claimed that our original concepts, as we vaguely apprehended them, did not cover those examples; nor should we merely make an ("exception-barring") restriction of the domain of application of the theorem so as to exclude the counter-examples. Rather, the proof must be re-analysed in the light of the counter-examples: in this way, we discover hidden lemmas, and build into the statement of the theorem the hypotheses essential for its validity.

With these maxims about how to do mathematics, few would disagree, despite a certain truculence in Lakatos's manner of arguing for them. He has, however, another thesis, about how mathematics should be presented. He deplores the deductivist Euclidean style, in which a set of complicated definitions and axioms are stated at the outset, without explanation, and complex theorems follow, with their proofs in the barest form. Exposition in this manner conceals what is required for understanding: instead, it should reflect the actual history of the problems, "rationally reconstructed", so that the motivation of the definitions, axioms and hypotheses of the theorems becomes apparent. This second thesis, about mathematical style, is more tendentious than the first, but has a great deal to be said in its favour. Certainly it impedes understanding when a definition is given without any illustration of the cases to which the term so defined does and does not apply, and without any explanation why it should be framed as it is; and certainly also the historical information embedded in most mathematical textbooks is often mythological. How much difference would be made to the best mathematical expositions by the adoption of

Lakatos's recommendations depends on how much is allowable as "rational reconstruction".

The most important question, however, is how far Lakatos intended to assert, as well as a methodological and a stylistic thesis, a philosophical one. Most people's first reaction to Lakatos's work is to say that the situation he describes is one likely to prevail in a branch of mathematics in its early stages, before it has attained the condition of an axiomatised theory, but not when it has reached maturity. On this view, Lakatos's observations have no philosophical consequences: they describe how we do, or can best, arrive at a developed theory, how we can make mathematical discoveries, not what such a theory is like when we have succeeded in framing it. There are, however, passages (pages 100 and 138) suggesting that Lakatos took a quite different view, namely that the process of finding counter-examples and re-analysing proofs in the light of them is never-ending, or, at least, that we can never know that we have reached an end.

This thesis, if accepted, would indeed be of critical philosophical importance, since it would demand, though it would not itself provide, a revision of most of the known accounts of mathematical knowledge, if not of mathematical truth. Other passages (for example, p. 124), however, suggest that the process does terminate. The editors are more clearly of this opinion than Lakatos himself (pages 125-6 and 138n). They think that, by formalisation, one can dispel all doubt from the proof, and throw it upon the axioms: from these, however, it can never be removed. This leaves a big lacuna in the whole discussion: the character of doubt concerning the axioms of a mathematical theory is far from obvious. Thus, in the upshot, we are presented, in this book, with a piece of work which, although admirable as a historical study, is, from a philosophical standpoint, incomplete and inconclusive. Doubtless the delay in publication was due to Lakatos's awareness of this: had he lived, we should presumably have eventually had a more finished work.

Nevertheless, the book, as it stands, is rich and stimulating, and, unlike most writings on the philosophy of mathematics, succeeds in making excellent use of detailed observations about mathematics as it is actually practised.

Michael Dummett

Michael Dummett was Reader in the Philosophy of Mathematics at the University of Oxford from 1961-74, and has been Senior Research Fellow at All Souls' College, Oxford, UK, from 1974.

Ramifying phylum

The Biology of the Mollusca. By R. D. Purchon. (Second edition.) Pp xxv+560. (Pergamon: Oxford and New York, 1977.) £17.50.

ARISING from a common stock with the segmented annelids and arthropods, the molluscs proceeded to evolve along totally different lines, to attain in the cephalopods the culmination of invertebrate organisation. They did so from a basis of possibly secondary simplicity—this depending on whether or not the enigmatic *Neopilina* may be regarded as segmented.

Contemplation of the structure of early fishes might have led some contemporary evolutionist to predict developments in structural pattern that could lead to amphibious and eventually terrestrial success. Similar survey of the first obscurely crawling molluscs could have afforded no faintest indication of possibilities eventually realised in the torsionally produced gastropods, compressed and insinuating bivalves, and predacious, rapidly darting squids.

The consequences of the radiating evolutionary possibilities of primitive molluscan structure are admirably revealed in this second edition of a book which received all too little notice when first published in 1968.

Although a sizeable volume it cannot hope to cover the enormous extent of form, function and environmental

specialisation achieved by members of this intricately ramifying phylum, with convergence running wild to produce both snail-like bivalves and bivalve gastropods. The author has concentrated on groups or aspects with which he is most at home or which he feels are of greatest significance.

Almost complete adherence to the original pagination has prevented any extensive introduction of new material. Due note has, however, been taken of the recent work of Professor J. A. Allen on the Verticordiidae. These latter bring the septibranch bivalves into unquestioned association with the eulamellibranchs and exclude previous ideas about possible direct connection with the protobranchs.

The precise nature and course of the digestive processes in the bivalves continues to provoke investigation. Here, Professor Purchon provides a judicious review of the present state of the controversy, largely stimulated by the work of Dr Brian Morton, on the precise cyclic nature of these processes. He has also brought up to date his sections on the distribution, and mode of spreading, of gastropods on Pacific islands.

This new edition provides an admirable introduction to the advanced study of this significant phylum.

C. M. Yonge

Sir Maurice Yonge is Honorary Fellow in Zoology at the University of Edinburgh, UK.

Fusion research

Nuclear Fusion. Special Supplement, 1976. (World Survey of Major Facilities in Controlled Fusion Research.) Pp. 866. (International Atomic Energy Agency, Vienna, 1976.) \$48.

THIS large volume provides a unique insight into the magnitude and variety of the world's research and development effort in nuclear fusion. Following the false dawn at the time of the early Geneva Conferences, an immense amount of experimental and theoretical work by the plasma physicists has led to the construction of numerous plasma-confining devices, quite apart from more recent initiatives on the entirely distinct concept of laser-implosion devices. Now several laboratories, notably Argonne and Oak Ridge in the United States have embarked on long-range (20 years plus) development programmes of operating fusion reactors on the basis of the tokamak confinement principle, incorporating detailed development programmes in all the subsidiary technologies from ultrahigh power electrical supplies to tritium processing.

The World Survey first classifies programmes by country and laboratory; each entry specifies purpose, key personnel, main features, major results and future plans. Numerous perspective drawings of actual or conceptual reactor designs are included, the Americans, Russians, Japanese and Germans seeming to have the largest and most varied programmes. There follows a summary section classified by types of programme (confinement systems, plasma physics, heating techniques and fuel injection strategies, reactor considerations including materials research, and laser research—including laser-aided fuel injection into plasmas). There is an alphabetical index of more than 3,000 key scientific workers.

It is a major achievement to have assembled so much solid information in standardised format from so many sources. The scale and scope of the work described implies the growing optimism that nuclear fusion represents a genuine hope as an energy source for the twenty-first century.

Population analysis

Spatial Population Analysis. By P. H. Rees and A. G. Wilson. Pp. 356. (Arnold: London; Academic: New York, 1977.) £27.50; \$35.50.

ALL would agree with the authors' aim to provide good methods of population analysis for effective social and economic planning; this detailed and thorough text provides such an essential basis. In their preface, the authors warn the reader that he must face considerable conceptual difficulties in acquiring the skill, but comfort him by claiming relatively little demand on formal mathematical knowledge apart from algebra and an elementary knowledge of matrices. Nevertheless, this is a formidable text that needs to be painstakingly worked through to follow the argument.

The strength of the text is claimed to be that for the first time the analysis takes full cognisance of migration through the "use of new and powerful conceptual and mathematical tools". Such recognition of the importance of migration is welcome, since it has received scant treatment in some recently published work, a strange weakness in a world of growing mobility.

The text itself is arranged in five parts, each well introduced, and the argument subsequently explained and documented. The first part introduces current population models and their associated problems: here the authors introduce one of their fundamental features—models based on age groups and not life-tables, a basic divergence from the work of Keyfitz on the mathematics of population. It is also pointed out that although concentration is on theoretical concepts, examples using real data are introduced to illustrate the argument.

The second part introduces the concept of "population accounting" and is illustrated by reference to aggregate populations. The third part is devoted to the development of realistic population models, followed in the fourth part by the putting forward of the concept of life-table accounts to demonstrate that spatial dimensions may be added to conventional life-table analysis to make associated models more systematic, consistent and rigorous. The final, fifth, part summarises the new methods and their applications as well as their relationship to development in other fields.

The authors have been careful to make sure their work can be applied empirically by limiting themselves to commonly available data, although

they have interwoven their own work with that of Lexis, Pressat, Rogers, Stone and others already accepted among demographers.

With page after page of mathematical formulae and matrices, the publishers have faced a monumental task in producing the book in present conditions at a realistic price. It is no wonder that the book is nevertheless expensive.

R. E. H. Mellor

R. E. H. Mellor is Professor of Geography at the University of Aberdeen, UK.

γ -ray astronomy

Gamma-Ray Astronomy. By E. L. Chupp. (Reidel: Dordrecht, The Netherlands and Boston, Massachusetts, 1976.) Cloth Dfl 105; paper Dfl 50.

THE title on the cover of this book reads *Gamma-Ray Astronomy* but inside a subtitle, *Nuclear Transition Region* has been added. This uncertainty as to the scope of the book extends into the text and gives an uneven quality to what is, otherwise, a valuable contribution to this field of astronomy.

The first chapter is a brief introduction and it is followed by a chapter on the fundamental mechanisms which produce γ rays. Those processes which lead to line spectra, such as transitions between excited states of nuclei and the annihilation of positrons, are treated very thoroughly. Presumably for the sake of completeness this chapter also deals with mechanisms such as Compton scattering, *bremstrahlung* and the decay of neutral pions, all of which lead to the production of continuous spectra.

The mechanisms discussed in chapter 2 are then used in the next chapter to predict the γ -ray emission which may be expected from astronomical sources. The inclusion of a chapter on predicted fluxes was perhaps necessary because of the paucity of experimental data in γ -ray astronomy, but this does lead to a certain amount of repetition in the book because some of the discussions are presented again when the experimental results are described in chapter 5. The author's interest in continuous spectra seems to waver a little in chapter 3 and he provides only a brief discussion of the high energy γ -ray emission from pulsars and supernova remnants, and makes no mention of extragalactic sources such as radio galaxies and quasars. Chapter 4 is concerned with the interactions of γ rays with matter and is included as an introduction to

experimental problems in γ -ray astronomy.

Chapter 5 is devoted to observational results. As in chapter 3, the treatment of the sources of continuous spectra is not consistent; for example, no mention is made of the many measurements of the pulsar NPO532 in the Crab nebula although the unsuccessful searches for γ rays from extragalactic supernovae are described.

Chapter 6 deals with experimental problems in γ -ray astronomy and, appropriately, is the longest chapter in the book. It contains a comprehensive discussion of the background problems in a wide variety of detectors; if the quantity of data referred to does seem a little forbidding to the newcomer to the field, it will at least remind him of the need for technical innovation if this branch of astronomy is to make significant progress.

This is the first book to place the correct emphasis on the experimental problems in γ -ray astronomy and will therefore be invaluable both to the newcomer and to the experienced worker in this field.

Awards

The Ciba-Geigy Drew Award in Biomedical Research (\$2,000) will be granted annually. The topic for the initial awards and symposium is Viral Etiology of Cancer and the recipients are Robert C. Gallo, and Fred Rapp. The first symposium will be held on 20 October 1977.

The André Lichtwitz prize (9,500 French francs) is awarded every year by INSERM for French or foreign scientists (or a team) who have specially distinguished themselves in research on calcium and phosphorus metabolism carried out during the previous year, whether in the clinical or more fundamental fields. Conditions of entry for the 1977 prize are obtained from INSERM. Applications must reach the Director of the INSERM (c/o Mlle. C. Chirol, 101 rue de Tolbiac, 75645-Paris Cedex 13, France) by 30 June 1977.

The 'Life Institute' prize (EDF Foundation), of 300,000 F, was shared by a Japanese research team represented by Makio Ushida, and a Swedish chemist, Sören Jensen. The international jury, rewarded the Japanese for their work on the toxicity of methyl mercury, which is the cause of Minamata Disease. Sören Jensen was rewarded for his work on the polychlorobiphenyls. These organic derivatives are used in paints, lubricants, rubbers and so on. As they are fat-soluble and are not biodegradable they tend to accumulate and may contaminate food processing plants.

Vacancies

Two vacancies exist in the International Commission on Zoological Nomenclature owing to resignations. Nominations for candidates for election to the vacancies should be sent to the Secretary, International Commission on Zoological Nomenclature, c/o British Museum (Natural History), Cromwell Road, London SW7 5BD, United Kingdom, within three months of the date of publication of this notice in the *Bulletin of Zoological Nomenclature*. Candidates must be eminent scientists, irrespective of nationality, with a distinguished record in any branch of zoology, who are known to have an interest in zoological nomenclature.

Nominations must state the name, date of birth, nationality, field(s) of specialisation and qualifications of each candidate, and the name(s) and status of the nominator(s). A list of the candidate's publications and his *curriculum vitae* would also be helpful.

2 June 1977

Technology transfer at DOI

THE latest Report on Research and Development from Britain's Department of Industry (DOI), for the two years 1974–1976 (HMSO; £1.25), comes just at the time that Sir Ieuan Maddock hands over the post of Chief Scientist in the Department to Dr Duncan Davies, who was until recently in overall control of research at ICI. Research and development at DOI is not about to undergo sweeping changes as a result of this move, as the strategy for the next few years is bound to be evolutionary, but the report is valuable as marking more than just the end of one man's chieftainship—the Rothschild reorganisation of governmental support for science was also completed in the period under review, so it is possible to look at the whole new policy-making structure erected in the past few years.

The department now spends roughly £100 million per year in industrial research and development, and of this about one-half goes into DOI research establishments (which include the National Physical and National Engineering Laboratories), and other governmental organisations. The remainder goes to industry, either directly (largely to the aerospace industry for the reduction of fuel consumption and noise) or indirectly by way of Britain's subscription to the European Space Agency of which DOI pays the major part. Away from the aerospace field, expenditure is widely scattered over subjects ranging from quantum metrology and waste recovery to cloth cutting for the garment industry. Research is guided by means of eight requirements boards, the membership of which is roughly half industrial, half academic and governmental.

The research and development aspect of the work is obvious and it is DOI's expressed intention to place more of its contracts out with industry itself, which should be welcome news for the not-exactly-buoyant industrial research sector. It should also place the governmental research establishments firmly on their

mettle to adopt aggressive programmes of their own, reaching out, as did Harwell several years ago with some success, in the hope of tapping new sources of funding. This will be a long haul. It is clear, however, that as the requirements boards begin to develop greater selectivity and acquire greater influence, they will want to avoid any pretensions that they act in some way as a sort of proxy management for the research establishments.

The other major aspect of DOI's task is to transfer technology out of the laboratory and into the factory. It has recently been a departmental theme that the national emphasis on aerospace has been to the detriment of the low-technology or small industry where the largely unmet demand is for modern rather than highly advanced technology. And it is in this field of the application of already existing technology that very interesting second careers are to be made.

We have repeated almost *ad nauseam* that the civil-servant scientist and technologist finds him or herself in an unfortunate bind in that seniority in the service leads, for most, not to more broad administrative and managerial responsibilities but to more of the same thing, often against a background of rapid and difficult-to-absorb change. In the field of technology transfer there could well be scope for the gainful employment of many who are at the present doing little more than marking time. For the skill that is most needed is not intellectual brilliance but wide experience. To be sure, not every one-time scientist or technologist is going to be able to develop into an ideas broker, capable of getting, in the most unabrasive way, into the textile mills or the workshops under the railway arches to hear about old problems and to talk about new techniques. But there must be some who would relish the challenge of such a job. Maybe DOI's new Chief Scientist will be tossing such an idea into the laboratories under his wing. □

Séveso solicitude

Alastair Hay visits Séveso and finds political as well as technical problems

IT IS ten months since the ICMESA chemical plant reactor exploded discharging tetrachlorodibenzo-*p*-dioxin (dioxin) over a large section of the Italian town of Séveso. Though considerable progress in the reclamation of the largest residential portion of the area is now apparent, the record of success has not extended to actual physical destruction of the dioxin present in the contaminated material collected. Vacillation over the methods to be adopted is caused by several factors: a paucity of relevant scientific data, hostility by Séveso residents to some of the methods which the Lombardy regional government has proposed, and indecision in government circles at the regional and national level. At regional level the preferred course of action seems to be destruction by incineration, but Séveso residents view construction of the incinerator with alarm and this could prove electorally damaging to the political parties concerned.

Professor Augusto Giovanardi, coordinator of the Decontamination Commission appointed by the Lombardy regional government to supervise operations at Séveso, says that according to measurements made by the commission between 300 and 500 grams of dioxin were deposited in the most contaminated area (designated zone A) and that some 10 grams were present in the less affected zone B. He dismisses the suggestion made by a British scientist, Dr Donald Lee, that up to 130 kg of dioxin could have been produced in the reactor explosion. However, Giovanardi acknowledges that neither his commission nor Givaudan had been given permission by the Italian courts to check the reactor contents. This analysis was being carried out solely by scientists employed by the judiciary.

Seven sections

For the purpose of decontamination policy zone A has been divided into seven sections. Areas A1-A3—those nearest the reactor—are the most seriously contaminated, and contain about 80% of the discharged dioxin. A4 and A5 are areas of 'medium contamination'; A6 and A7, the least affected portions of zone A, housed 80% of the residents evacuated from the area by the local authority. Consequently it has been sections A6 and A7 which have received most attention by the authorities. Giovanardi explains

that buildings in the area have been decontaminated by a process of vacuum cleaning and washing with solvents. "Most of the soil and vegetation from the area had been stripped away two weeks ago", he says, "and the pavements and roads will be the last portions to be cleared". He adds: "We hope that the people with homes in the area will be able to return to them sometime in the months of June to August this year".

Concurrent with the decontamination work in zone A the commission has been working in zone B, which may yet have to be expanded. Here the residents have been asked to abide by certain rules to minimise personal exposure to dioxin. Children leave the area for the daylight hours, and women in the first trimester of pregnancy are advised to move from the district until the foetus is at least three months of age. With the work on sections A6 and A7 now nearing completion Giovanardi says the commission "is now applying the same operation to the houses, vegetable gardens and so on in zone B that we have used in A6 and A7". Contaminated soil and vegetation from these areas is being deposited in the 'medium contaminated' sections A4 and A5. The vegetation is to be incinerated, but the soil may well be left unprocessed in the hope that microbial degradation will reduce the dioxin concentrations to acceptable levels.

Whereas the consensus of scientific opinion is that the soil should be removed from zones A6 and A7 and definitely from the 'heavily contaminated' areas A1-A3, opinions differ on the methods to be applied to degrade the dioxin present. Incineration is apparently the approach favoured on theoretical grounds by some members of the commission, but this view is by no means universal. Other scientists are conducting trials on photochemical decomposition of dioxin, solvent extraction of the chemical (from the soil) and degradation by steam distillation.

The most vehement opposition to the incineration proposal and to the plans to construct an incinerator on the site of the ICMESA plant comes from the Séveso residents. They have had enough. If the incinerator has to be built, they argue that it should be built somewhere else. They know that incineration of the soil on the scale proposed will be an enormous under-

Barrier to progress?

taking. It will be an untried process and they claim that they are to be the 'guinea pigs' of the regional authority. In the past month they have mounted a demonstration in Milan to protest against the incinerator's construction and gunmen have broken into the office of the health officer at Séveso, shooting him several times in the legs.

Information relevant to the handling of dioxin-contaminated soil has been procured for the Italian authorities by Professor Barry Commoner from the US Department of Defense. On a visit to Italy in February and March, Commoner expressed concern and disappointment at the measures being adopted. He wrote that it was evident that "a systematic examination of alternatives [for degrading dioxin] has not been carried out" by the Decontamination Commission, and much of the decontamination work was "unnecessarily confused". Asked about Commoner's criticisms, Giovanardi's response is that whereas incineration appears to be the most feasible degradative process, his commission is considering all alternative procedures.

Government Commission

Last year the Italian Government appointed its own Commission to assist the local authorities at Séveso and the regional government in Lombardy. The Under Secretary of State for Health, Dr Fernando Russo, is the commission's president. As such he has the responsibility for collating all the available information on dioxin both nationally and internationally. He says there is "no evidence available on the complete destruction of dioxin. We are still searching for this evidence on an international scale".

Russo says that the final aim of all the authorities is to reduce the dioxin

levels to zero. The Ministry of Health convened a meeting in Rome recently to assess the situation at which a whole series of programmes were discussed. Many problems remained unsolved. Séveso has been a very bitter lesson for Italy. It has forced the government to review its legislation on industrial hazards, pollution control, toxicology and food additives, amongst other things. The message has been rammed home that 'prevention is better than cure'. Russo says Italy would like legislation on pollution control in particular to be a European Community measure, for national legislation on this issue "might provoke reprisals" and force multinational companies to go elsewhere.

As for the specific pollution problem at Séveso, Russo is in no doubt that ICMESA's owners Givaudan, as a big company, "will more or less have to pay" for the damage they caused, estimated now to cost 113 billion lira—about £80 million. Givaudan states that this figure seems "extremely large".

Just to ensure that they do receive payment, the local authorities in and around Séveso, the Lombardy regional government and the central government are all involved in litigation for damages against Givaudan. The company, they claim, had inadequate safety features operating in the trichlorophenol reactor. And to compound the problem, when the accident occurred the ICMESA management provided insufficient information on the pollution hazard. As a result many people were put to unnecessary risk by their exposure to dioxin for the two weeks before residents were evacuated.

Central matter

This two week period of exposure is central to the health problems of the Séveso population and to the issue of

abortion for the pregnant women exposed to dioxin. Although Russo claims that the Italian government wasn't against abortion for these women and that the opposition came from local doctors at Séveso, he has the impression that it hadn't been too difficult for the women to procure legal terminations.

This impression is not confirmed by Ms Adele Faccio, the Radical Party Member of Parliament for the constituency of Genoa. She was in the Séveso area in July and August last year and, as a result, has been particularly concerned about the question of abortions for the Séveso women.

"It was extremely difficult for these women to obtain legal terminations", she declares emphatically. To substantiate her claim she cites the figures for the abortions performed on the women. "Only 30 women had legal terminations", she says, "whereas twice this number have had illegal abortions. The illegal terminations were performed by 'women's self-help groups' for cases where the foetus was not older than ten weeks. For women in a more advanced state of pregnancy it was essential to send them abroad for an abortion".

But if legal abortions have proved difficult for the Séveso women, there is some relief in Italian medical circles over the results of the examinations performed on the foetuses from those women permitted legal terminations. These examinations were conducted by Professor Alfred Gropp and Dr Helga Rehder of the Lubeck Medical School, Germany, and Professor Francesco Céfis and Dr Laura Sanchioni of the Istituti Clinici di Perfezionamento in Milan. Of the 34 foetuses examined only one showed any signs of abnormal development. As with most of the foetuses examined, however, this one embryo was badly macerated—a common situation with induced abortions.

The results must therefore be interpreted with great caution. They could be suggestive in this one instance of foetal Down's syndrome. This, however, is a not uncommon foetal abnormality in most populations. Some UK clinicians think it is unlikely to be due to dioxin. Professor Gropp and his colleagues claim in a report to the Lombardy Regional Health Authority that "the results of the embryo-morphological studies do not give any hint for damage brought about by the action of exogenous agents (dioxin)". They add the rider, however, that the negative result must not necessarily mean that dioxin "does not bear a risk for the mother and foetus". The examinations had certain inherent limitations: minor malformations and particularly organ damage

are not detectable in the very young foetus; only a limited number of cases could be studied, and most of these embryos were incomplete and of different gestational age.

Professor Gaetano Fara, chairman of the Lombardy region's Health and Epidemiology Commission for Séveso, adds a further qualification to the interpretation of these results. He admits the foetal examinations cannot be interpreted in the context of a true epidemiological survey; they are an analysis of data to hand. He adds that, for a true epidemiological survey, the population would obviously have been much larger and more carefully monitored.

As for the eight children from the Séveso area born with abnormalities, Fara claims that statistics would indicate that this incidence of malformation is no greater than the average for the region. Some epidemiologists in the UK have expressed the opinion that because of the variation in the pattern malformations reported at Séveso it is quite possible that they are not due to dioxin. They add that, if the chemical was responsible for these abnormalities it would be reasonable to expect a more consistent pattern in the defects observed.

Even though some of the medical results appear to be reassuring, Fara insists that they still consider the Séveso residents to be a 'population at risk'. He said that a preliminary report on the children from Séveso based on three visits to doctors had revealed no immunological damage in this group, compared with their peers in a non-contaminated area. Similarly chromosomal studies performed on the 34 aborted foetuses by Dr Luigi de Carli at the University of Bafia had revealed no genetical deviations from the accepted norm.

But Fara does admit that the cases of chloracne reported represent an area greater than that officially designated as being contaminated. He acknowledges that it is worrying, but adds that of the 525 cases of reported chloracne, only 1 in 4 were confirmed on subsequent re-examination. In view of the toxicity of dioxin, however, the regional authority is to embark on a large scale epidemiological study of the area. Fara says that the population will have to be monitored for years to come.

If Professor Giovanardi's predictions are correct the Decontamination Commission will not complete its programme to bring dioxin down to an acceptable level before 1980. By this time most of the residents will have returned to their homes, but as a population still 'at risk' fears about dioxin will still be a part of their lives. □

Scientists and education in Poland

Social change in Poland is affecting the country's science and education policies. A **Special Correspondent** reports

DURING periods of heightened social tension, general issues dominate science and education policy, as the present situation in Poland illustrates. The main problems which face the country are political rather than economic. The beginning of a wave of repression against the participants in strikes in June 1976 (*Nature*, 5 August 1976) followed the abortive decision to raise prices significantly. On 23 September 1976 the Workers Defence Committee (KOR) was formed by a small group of courageous people. It made several demands; unconditional amnesty for all sentenced for their participation in strikes and demonstrations; provision of appropriate jobs for all workers dismissed from the factories and restoration of long-service privileges; disclosures of all repressions including beating by the police while in custody, false accusations and confessions coerced by force, unlawful conduct of courts and so on; and the setting up of an independent parliamentary committee to investigate all facts related to infringement of human rights.

Acting openly in spite of the fact that it is illegal, the KOR, consisting of 23 members, enjoys considerable support. It is collaborating with a fairly wide group, mainly students and recent graduates drawn from participants in the student riots of March 1968 and from the Clubs of Catholic Intelligentsia and, to a lesser degree, from the Scouting organisation. It is their devoted work that enables KOR to collect and distribute money (about 500,000 zlotys up to the end of March); to gain access to the people involved

and to monitor the court proceedings; and to publish and circulate KOR's *Bulletin* (nine issues so far) and other documents. KOR's appeal for public support has been answered by many letters of protest to the Polish Parliament, from more than 2,500 people. They include 730 students from the University of Warsaw, 520 from the University of Krakow, and 285 from the Catholic University in Lublin.

KOR is in no sense a political party: it has no political programme and the political opinions of its members and collaborators differ considerably. None of its activities is directly political, and this may be the source of its strength and early immunity. The tactics chosen by KOR have been effective; its very existence has structured internal political life and provided a new pattern of defence of civic rights under the communist regime. This is manifested in the growing self-assertion of diverse social groups in exercising their rights under existing laws. Writers have produced a first unofficial literary journal *Zapis*, a large type-written volume of poetry, stories and criticism. A number of political programmes and groups have appeared, some of them critical of KOR.

Scientists have also been active. Thirty-four professors, most of whom have not raised their voice in public before, sent a letter of protest to Parliament. They included many well-known scientists and members of the Polish Academy of Sciences (PAS): W. Kemula (Chemistry), W. Miemierko, J. Kielanowski, W. Kunicki-Goldfinger, E. Domanski, A. Brzoza, M. Nunberg

(Natural Sciences), I. Chmielewska (Biochemistry). Another letter was signed by about 300 younger scientists and artists. Although these letters are the most visible protestations, others are no less significant. During the General Assembly of the PAS on 17 December 1976, for example, several members of the Academy opposed the established procedure which reduces the role of the Assembly to a purely formal acceptance of candidates proposed by the Praesidium (which in turn is completely dependent on the political authorities). Three recommended candidates were not elected. Among them were Professor J. Szuba (favoured personally by Mr Gierek, the Secretary of the Party) and Professor Z. Rybicki, the Chancellor of Warsaw University.

Teachers' protest

Some letters of protest were signed by school teachers. In Poland the teaching profession is particularly weak because for many years it absorbed weaker graduates unable to find jobs of higher social standing and independence from administrative bodies; also the teaching profession consists almost entirely of women. The teachers' publicly expressed protests were followed immediately by repressions. In the Tadeusz Rejtan secondary school in Warsaw, for example, six teachers were given dismissal notices (three of them are to be transferred to other schools, and three have been asked to retire early; these decisions have not yet been implemented). Ironically Tadeusz Rejtan was the member of Parliament who fought against the first partition of Poland in 1773. The action against teachers immediately provoked a new flow of protests, this time from the school's students and graduates.

No similar case of repression of older members of the scientific community is known to this correspondent,

Miloslaw Chojecki, a nuclear physicist, and Piotr Naimski, a biochemist, were recently arrested as part of a new campaign of the Polish Government against the Workers' Defence Committee. In all, some 25 activists were arrested, apparently as a preventive measure. The recent death, in mysterious circumstances, of Krakow student Stanislaw Pyjas has led to renewed agitation against alleged police illegalities, and it is thought that the arrest of the activists was intended to neutralise this opposition. In spite of the arrests, however, the agitation, and demands for a public inquiry into the death of Pyjas, are still increasing.

Warsaw University library

and the authorities try not to create martyrs. The situation for younger scientists, however, is different. The case of Mr Chojecki, who was dismissed from the Institute of Nuclear Research, has already been mentioned in *Nature*. More recently Mr J. Celinski, who was dismissed from the University of Warsaw, brought his case to court. The court upheld the decision of the university because, as formally stated in the judge's justification,

Each department and its chief is responsible for the results of work and is free to choose employees with appropriate professional qualifications. These qualifications include sometimes . . . political criteria . . . and the political convictions of the plaintiff disqualify him from being a member of staff of the University of Warsaw.

These actions against teachers and scientists are of course relatively mild. Under present international circumstances, however, it is precisely the activity of KOR that makes the escalation of repression difficult. Each country has its own scale of values and measures of tolerance which form an ethical frame in which the political repressions in Poland should be judged.

Another major determinant of the situation is the plan for a new educational system. Parliament passed a curious bill describing the general shape of future changes but without specific decisions. The ten-year school, the basis of the new system (see figure), is not a secondary school in the ordinary sense, because entry to the university is guaranteed only for the winner of school olympics (a special type of competitive examination) and for those who have a record of "two years of excellent professional work or two years of impeccable military service".

The most striking feature of the new system is that most future students will have to complete military service before entering university. However, there will be other options for students leaving the ten-year school, ranging from six-month professional courses to two years of further general education. One can expect therefore a highly differentiated level of readiness for university studies which must impinge on the performance of the universities. The further feminisation of the universities would also follow. The fraction of women in institutions of higher education is about 52%; arts faculties have 77%; education 74%; medicine, with some measure of preference for men, has 64%; engineering, the least feminised faculty, has 34%.

Implementing the plan

Preliminary steps for introduction of the new educational system have

already been taken. About 70,000 acting teachers are being taught in special schools or special faculties of universities. It is commonly accepted that the courses they offer are poor, but they are entitled to confer masters degrees.

No one can deny that the present schooling system has serious shortcomings and does not serve the social needs of Poland. However, it is also true that discussion of the new system was deliberately channelled on to such problems as curricula, teacher training, availability of buildings and so on, and was made to bypass the evident political motives underlying the reform. The first of these is the failure of the schools' ideological influence; both teachers and students have adopted a sort of newspeak understood by both sides to be meaningless. Second, the schools do not provide appropriate political filters; in spite of some incentives, the number of students from workers' and farmers' families is not increasing and these students are in no sense more loyal to the party than other students. The authorities hope that the new system will provide more effective social indoctrination and more reliable political filters.

It is still unclear when implementation of the new system (planned for 1978) will begin. The system is very costly and its social price—the loss of experience accumulated by the existing system—is even higher. Postwar social changes in Poland opened the possibility of study for all who desired it, so making possible the social promotion of all gifted people from the working class. The byproduct of this process, however, was a significant decrease of the working class's own intelligentsia, a group which contributed most to the 'striving for education' within its class. Those gaining education often break their ties with their previous social environment (formally too they are not considered as members of the working class any longer) and constitute a very conservative group of people who, as they see it, have nothing to win and everything to lose.

There are additional reasons for the declining attractiveness of university studies for young people from the working class. Nowadays students who cannot rely on their families for support are in a worse position than their colleagues in the 1950s, because of a decrease in the real value of scholarships. More importantly, graduate prospects are not very bright: it is not easy to find appropriate jobs, salaries are relatively low, and there are serious difficulties in getting a flat (formally graduates have a high priority in the queue for flats, but the overall short-

The Palace of Culture, seat of PAS

age makes this privilege of negligible value). Usually the new graduate is worse off than his less gifted friend from the primary school.

The political control of universities is exercised primarily by the careful selection of staff. No one can be engaged without the consent of the party organisation and without a good record from the police. The admission to post-graduate studies is similarly controlled, and several people who pass the examination are not admitted because of their or even their parents' political attitudes. In the recent enactment of the Ministry of Science and Higher Education (December 1976) it is openly stated that to be admitted to post-graduate studies the candidate has to "display proper ideological and civic attitudes". The chosen faculty has little relevance in this regard and candidates in social sciences and, say, medicine are treated on the same basis.

The fate of the new movements which are changing considerably the pattern of internal politics in Poland and, more generally, the immediate future of this country, are closely related to the whole human rights issue. This makes the proceedings and the results of the Belgrade Conference vitally important for Poland. At best one can expect some softening of the political line, and a more elastic and realistic approach to the needs and demands of people which could lead to a better economic performance. At worst one can foresee a partial return to cold-war policy with the rise of police power and a further widening of the gap between the rulers and the ruled. But even in this case the experience gained during the last few months could play an important role: Polish society has learned a lesson which it will be difficult to erase. □

USA

The threat to academic science

Colin Norman reports from Washington on a study of the state of US academic research

ACADEMIC scientists in the United States have been complaining bitterly during the past few years. Declining budgets and increasing amounts of red tape are putting severe strains on the country's research system and gradually eroding the quality of basic research, they claim. Yet American science remains outstanding by any measure: total funds for research and development are expected to reach about \$41,000 million this year, and scientists from the United States walked off with every Nobel Prize awarded last year. So do the complaints have any real basis, or are they simply self-interested pleas for more money?

According to an impressively detailed and closely argued report published this week*, there is indeed plenty of cause for concern about the health of academic research in the United States. Written by two social scientists working with a grant from the National Science Foundation (NSF), the report reaches this ominous conclusion: "The discoveries that are now being made are based on research initiated many years ago, the system is operating on momentum, but there are disturbing signs that the momentum generated during World War II and for 25 years thereafter has been halted. An important national resource may be eroding and the nation is faced with the possibility that it will lose scientific and technological leadership in many fields".

The authors of the study, Bruce L. R. Smith of Columbia University and Joseph R. Karlesky of Franklin and Marshall College in Pennsylvania, base that lugubrious assessment on a number of factors which are hurting the universities in general and university science in particular. Their chief message is not that academic science is in imminent danger of collapse, but that a number of far-reaching changes are taking place in the research system. "Failure to deal adequately with the long-term adverse trends could generate a decline from which recovery will be difficult and protracted", they warn.

In particular, Smith and Karlesky suggest that the problems afflicting university research could lead to

greater stratification in the higher education system, with fewer universities conducting research of the highest quality. There could also be a weakening of the traditionally close links between research and teaching, and funding constraints could lead to less support for innovative and speculative research, they warn. But the potential changes are not all bad, for Smith and Karlesky note that in 1967 the between universities and industry, after a considerable period of arms-length relationships has begun to take root again".

The most obvious problem affecting academic research is that federal support for research and development abruptly shifted gear in the late 1960s, moving from a period of burgeoning growth to a period in which total funding failed to keep pace with inflation. Smith and Karlesky cite figures, for example, which indicate that federal expenditures on basic research dropped by about 15% in constant dollars between 1968 and 1976. And that abrupt shift coincided with a turn for the worse in the general financial health of the universities as many sources of public and private funds began to dry up while overhead costs began to increase by leaps and bounds.

Superimposed on that trend of shrinking total support has been a marked change in the nature of federal funding for academic science. Smith and Karlesky note that in 1967, the federal government spent \$1,301 million to support specific research projects in colleges and universities, but another \$1,022 million was provided in the form of general research support (block grants to institutions, graduate traineeships and grants for improving general scientific capabilities). But by 1975, that pattern had changed dramatically: support for specific projects had increased to \$2,222 million while general research support had dropped to only \$567 million. "This substantial decline in institutional funding means that universities have at their disposal less discretionary money to fill gaps, start new exploratory studies . . . and meet other special and changing needs". In short, universities have lost considerable flexibility in the use of federal research funds.

A major impact of the decline in financial support has been a marked deterioration in the quality of scientific instruments and other laboratory equipment in the universities, as "a number of universities have postponed the replacement of equipment and deferred maintenance", Smith and Karlesky

suggest. They cite, for example, the case of one public university in the midwest which has been unable to provide any funds for scientific instruments for the past six years, and they suggest that the problem of replacing outdated instruments and poor facilities is now facing even the most prestigious universities.

It should be noted, however, that the NSF budget for fiscal year 1978, proposed by President Ford shortly before he left office, includes some \$38 million for upgrading instruments in university laboratories. The NSF budget is, however, encountering some difficulties in Congress, and it is by no means certain that even that small relief measure will be fully approved.

A second major factor affecting the health of university research has been a marked deterioration in the academic job market for young scientists, as university expansion abruptly ceased in the early 1970s and the proportion of faculty members with tenure has increased sharply. Though there are significant differences between universities and between different fields of science, Smith and Karlesky report that the proportion of faculty members occupying tenured positions increased from 47% in 1969 to 65% in 1973. Moreover, according to a survey conducted by NSF, the tenure ratio in 1974 varied from a low of 59.1% in physiology to a high of 80.7% in chemical engineering.

"There is a growing uneasiness that the career pipelines may be too restricted and that determinants other than excellence are increasingly controlling career patterns", Smith and Karlesky report. They suggest, moreover, that "the decline in research opportunities for young investigators will be one of the most serious threats to the momentum of university research over the next decade". One noteworthy impact of the tenure logjam is, in fact, already showing up: the proportion of young faculty members (those who have held a PhD for less than seven years) declined from 43% in 1968 to 27% in 1975, and a further decline is anticipated by 1980.

As for enrolments in graduate departments, there was a major drop in the physical sciences and engineering in the early 1970s, while enrolments in the life sciences and the social sciences continued to increase. In some institutions, Smith and Karlesky predict that the rapidly shrinking numbers of graduate students could lead to decisions to drop some PhD programmes, a move which would force a painful choice between continuing to mount a research effort in the absence of graduate students or reducing re-

**The State of Academic Science* (Change Magazine Press, New Rochelle, New York; \$5.95).

search efforts to concentrate on teaching undergraduates. Such a decoupling of research and teaching functions would represent a significant departure from the traditional university role, but Smith and Karlesky note that some university departments are already contemplating whether to continue as research centres.

One of the major findings of the study was that recent trends in funding and enrolments have been felt most keenly by less distinguished departments and by less distinguished investigators. "In contrast", Smith and Karlesky report, "the leading science departments have tended to retain their relative strength . . . the downward trend has not appeared uniformly throughout all second-rank institutions, and the indicators of trouble have not always reached an advanced state. But the signs are sufficiently clear to warrant the conclusion that a very rapid deterioration in the relative position of many weaker departments could well occur in the near future".

In a sense, Smith and Karlesky note, it is "highly reassuring that our system of awarding research grants and contracts according to scientific merit appears to have achieved its aim in making certain that pre-eminent investigators are able to continue their work, and in most cases with adequate support". Nevertheless, the increased stratification in university research departments and the possibility that some second-rank institutions will drop research all together, raises a number of fundamental questions.

Although PhD programmes probably over expanded during the 1960s and "some of the research undertaken a decade ago was of less than first-rank quality", how far should the drift toward fewer and fewer outstanding research departments be allowed to proceed? Smith and Karlesky argue that "it is possible that the competitive elements in the system could be undermined if there were too few universities fully equipped for pre-eminent research. The nation would then be forced to rely on a narrow base of dominant centers".

In any case they argue that the trend "towards fewer universities and departments able to mount first-class research efforts will continue so long as federal research support remains essentially level, which is likely to be the case to some extent. Universities may be able to preserve their research missions by achieving a functional division of labor among themselves and by developing highly specialised research programs. But there is a certain minimum coverage of basic science fields that a university must undertake to retain its research vitality". □

200-mile zones: the threat to marine science

AS THE sixth session of the gruelling Law of the Sea Conference opened in New York last week, the National Academy of Sciences warned that the latest draft treaty could "cripple" marine scientific research. The Academy's warning, contained in a letter sent to Elliot Richardson, head of the US delegation to the conference, claimed that oceanographic research is in fact already being seriously hampered by restrictions imposed by some coastal nations.

The chief concern is that the draft treaty now under discussion (called the Revised Single Negotiating Text, in United Nations parlance) would give coastal states the right to regulate scientific research conducted within 200 miles of their shores. Since the coastal regions contain some of the most interesting oceanographic phenomenon, such as the major currents, virtually all of the oceans' biological activity and most of the world's undersea earthquakes, the Academy is worried that the treaty could put major areas of scientific research off-limits.

The revised single negotiating text would require that the consent of a coastal state be obtained before a research project is conducted within 200 miles of its shore. Consent could be denied for research which "bears substantially on the exploration of the living and non-living resources", involves drilling, or interferes with fishing or other economic activities. In addition, the coastal state would have the power to veto publication of research results from some types of projects, and it would have the right to halt a project if it believed that the research differed from the description given in the original proposal. Such restrictions could "cripple future marine scientific research which will be critical to the survival of the oceans and mankind", the Academy stated.

The Academy is therefore urging that the draft be modified to provide the following conditions for research projects conducted outside a nation's territorial water (which will probably be 12 miles), but inside the 200-mile 'Economic Zone':

- Freedom of research should be guaranteed except for carefully specified and limited types of projects.
- Specific criteria should determine whether or not a project requires prior

consent, and a definite procedure should be established for obtaining consent. The chief objective would be to ensure that no unreasonable or arbitrary restrictions are imposed.

- Freedom to publish and disseminate research results should be preserved.

In addition, the Academy recommends that the nation undertaking the research should be required to keep the coastal state fully informed of the nature, objective and schedule of a proposed project. The coastal state should also have a right to be represented in the project, and it should be given preliminary and final reports, a share in the data and samples, and assistance in interpreting the results.

To support its contention that the provisions contained in the draft treaty would seriously hamper research, the Academy cites evidence that a number of coastal states are already exercising strict controls over projects within 200 miles of their shores. In particular the Academy notes that "in the past year the records of the US National University Oceanic Laboratory System, which coordinates the activities of the academic fleet, indicate that about half of the scheduled cruises for work in waters over which other nations claim control have been cancelled because requests were denied, or have been hindered sufficiently to prevent the cruise taking place. Some requests were never acknowledged; sometimes approval came too late for the program to be successfully conducted. At least 18 nations were involved in one way or another in inhibiting science in this way".

In spite of the Academy's strong plea, oceanographers do not hold much hope that the final version of the Law of the Sea Treaty (if such a document ever emerges) will protect marine research from arbitrary or unreasonable restrictions. Coastal states sometimes claim that research vessels are used as a cover for military or commercial operations and their activities should therefore be tightly monitored and controlled. Moreover, since the oceanographic research fleet belongs almost exclusively to the developed countries, there's little immediate incentive for developing countries to grant freedom of research within their economic zones.

Colin Norman

USSR

● The gap between R&D and the implementation of results is a common complaint against the whole spectrum of Soviet industry. In most cases the problem is simply one of logistics, the reorganisation of production plans and the re-equipping of plants without interrupting quarterly production schedules. For high-vacuum technology, however, the problem is more complex, as there is no single body responsible for R&D in this field. According to a recent *Pravda* article, the Ministry of Chemical and Petroleum Equipment, is prepared to tolerate a "considerable" gap between production and requirements during the current five-year plan; the Ministry of the Communications Industry, which needs the results of research in this field, will not itself undertake it "considering it to be the business of other branches."

No single body or ministry, it would seem, has high-vacuum technology high on its list of priorities. It is the Cinderella of research subjects, and it is not surprising, therefore, that a report on a pilot cryogenic 1,000 kW electric generator at present under test in Leningrad speaks gloomily of the technical problems involved, although it suggests that plans for a similar generator of up to 2 GW are already in operation.

Last December, an article by G. Saksaganskii, Head of the All-Union Section of Vacuum Apparatus, suggested a way out of this problem: the establishment of a 'Scientific-Technological Union' which would be responsible for satisfying all requirements in this field, over-riding ministerial and departmental barriers. He put particular emphasis on the need for custom-built apparatus for highly specialised branches of research and industry, and praised the high levels attained in this field by foreign firms.

A recent edition of *Pravda* says that Saksaganskii's article provoked a wide response from readers in industries which have some concern with vacuum technology. All the letter-writers "unanimously" supported his proposal for a single organisation to deal with "specialised" production. But, it is claimed, the letter-writers went even further: not only does industry require a special body to ensure production, there should also be a unified authority in charge of R&D. A number of writers proposed that a special scientific council should be established in the Academy of Sciences of the USSR "to coordinate theoretical research in the field of vacuum technology and the practical implementation of their results". In

addition, steps should be taken to ensure that there are sufficient number of highly-qualified personnel in the field of vacuum technology. So far, it is said, the ministries whose sphere of competence touches upon high-vacuum technology have made no comment on these suggestions.

A press campaign of this type is a traditional precursor of a major change in Soviet policy, and the response to Saksaganskii's article seems

to reflect a genuine discontent. The Soviet press frequently carries eulogies of the benefits of centralised planning. The current state of the high-vacuum industry, is, however, a salutary warning of what may occur when a particular branch or field of development is somehow omitted or overlooked, if not in the plan itself then in the practical details of implementation.

● The Byelorussian SSR is traditionally one of the poorest areas in natural resources of the whole of the Soviet Union. When, some 20 years ago, a large oil-refinery was built at Novopolatsk, the site was presumably chosen for geographical reasons, being close (in Soviet terms) to the Comecon countries which would be provided by pipeline with Soviet oil. Since then, however, oil has been located in the Byelorussian Republic itself, giving a yield in 1976 of some millions of tonnes. Some seventeen oil deposits have been located to date, and new techniques have been developed permitting the exploitation even of those around Mazyr, where the geological structure is not amenable to standard drilling techniques.

The search for oil has also yielded serendipitous results: potassium and rock salts, lignite, mineral resources, building stone and also non-ferrous metals have been discovered, as well

as new sources of drinking and spa waters. This mineral wealth has come to light in an area of Irish-type rural economy where even collectivisation could not break the traditional dependence on potatoes, peat, and cattle-rearing. The development and exploitation of the new resources should provide a fascinating study in years to come.

● In May 1976, *Pravda* proclaimed that the ninth five-year plan (1971-76) had been a period of intense implementation of laser technology in the national economy, stating that every rouble invested in laser R&D has yielded some 4-5 roubles of income. A number of practical applications of lasers were noted, such as the hardening of dies and metal-working instruments and the drilling of jewels for watches; more significant however, was the fact that an actual investment to expenditure ratio was mentioned, a comparative rarity in Soviet reportage which presumably indicates a particularly favourable return.

Since the current five-year plan began, the media have described a number of more exotic uses of lasers. These range from acupuncture (a recognised medical technique in the USSR) to the use of a laser-beam guidance system for the blind landing of aircraft at night or in adverse weather conditions. At the Latvian State University's astronomical observatory, a senior scientific worker, Maris Abele, and a senior engineer, Augusts Rubans, recently received the Silver and Bronze medals respectively of the Exhibition of All-Union National Economic Achievements for developing a laser range-finder for tracking satellites and space-probes.

Laser irradiation has been used to encourage the germination of seeds, and the Central Aerological Industry of the Hydrometeorological Service has produced a special laser reflector which is now being used for tsunami research in the Kuriles. Laser direction finders for determining the direction of mine-galleries are in use and are being exported to other members of the Comecon bloc. Naturally, nothing is said in these enthusiastic reports about possible military applications of the laser, and the outsider is left free to judge whether this emphasis of the peaceful and diverse use of lasers covers a classified programme, or whether, as in the now-notorious case of titanium alloys, the prolific references in the open press are evidence that no breakthrough of military significance has yet occurred.

Vera Rich

BRITAIN

Advice and consent

The UK government last week published a White Paper (Cmd. 6820) in response to the Flowers Commission report on nuclear power and the environment. Chris Sherwell reports

THE bare bones of the UK government's 17-page response to the Flowers report give those involved in Britain's nuclear debate something to chew over, but many will wonder whether it was worth the eight-month wait. The White Paper says the government has decided to accept the bulk of the Flowers Commission's recommendations. The most concrete action proposed concerns management of radioactive waste. The government also plans to broaden the range of advice it receives, and wants more information made available to the public to facilitate full discussion.

It is only at the end of the White Paper and in the context of public discussion that one of the hard foci of Britain's nuclear debate, the demonstration commercial fast breeder reactor (CFR1), actually surfaces. The government accepts, says the White Paper, that before any decision is taken on CFR1, a special procedure for achieving a proper framework for wider public debate should be settled and announced. Presenting the White Paper last week, the Environment Secretary, Mr Peter Shore, confirmed that CFR1 would not proceed until there had been a broad-ranging examination and debate. He cited the machinery of the Public Inquiry Commission which was available but had not been used as one possible course.

In accordance with the Flowers Commission's recommendation responsibility for the management of radioactive waste has now been given to the Environment Secretary together with the heads of the Scottish and Welsh offices. The government has also accepted in principle Flowers' suggestion for a Nuclear Waste Management Advisory Committee, though it thinks that initially this need not be a statutory body. It also sees no need for a decision yet on the suggestion for a Nuclear Waste Disposal Corporation, but says it will reconsider this in light of a review of existing arrangements for the control of waste which the government is now, according to the White Paper, carrying out "as a priority task".

On both waste management and radiation standards the White Paper announces important changes affecting the control of research. The Secretaries

of State for the Environment, Scotland and Wales will "assume control of the waste management element" in the UKAEA's total R&D expenditure. And responsibility for initiating and co-ordinating research into the effects of radioactivity on man and the environment can, says the White Paper, "be more appropriately performed by a Minister than (as the Commission suggested) by the National Radiological Protection Board (NRPB)".

Mr Shore amplified on this reasoning last week only to say both research and policy were in the public domain. Responsibility would again be exercised by the three ministers acting jointly. So will "strategic responsibility" for monitoring environmental pathways lie with the ministers rather than with the NRPB. The government does accept the Commission's recommendation that the NRPB should have a statutory responsibility for advice on the adequacy of radiation standards for workers and the general public. The membership of the NRPB and its sources of finance are now being reviewed.

On nuclear safety generally the advice the government now receives from the Nuclear Installations Inspectorate, which is part of the Health and Safety Executive, will be supplemented by advice from another independent and expert source. This will be the Advisory

Committee on the Safety of Nuclear Installations, which is being set up in place of the former Nuclear Safety Advisory Committee to advise the Health and Safety Commission.

The pieces of this institutional jigsaw will be increased further by the creation ("pretty soon", according to Mr Shore) of what the White Paper calls a high-level independent body "to advise specifically on the interaction between energy policy and the environment". And there is still Mr Benn's Energy Commission to come.

The White Paper emphasises that a decision both on the choice of thermal reactor (which a junior minister at the Energy Department, Dr John Cunningham, last week said was "imminent") and on the further development of the breeder, would not of themselves involve any commitment to a large additional nuclear programme. "Much more significant" decisions will be needed in a few years' time, it says. A Green Paper on energy policy later this year is expected to spell this out in greater detail.

An air of caution is further conveyed early on in the White Paper. International discussions on nuclear policy, it says, mean that the government is "not yet in a position to give a final response" to certain conclusions and recommendation from Flowers on the two "central issues" of waste and security. That more than anything else confirmed that in nuclear power politics, almost nothing is final. □

Lords judgment

EUROPEAN policies are never easily come by, least of all in energy. With the next chance for the Nine to take a step towards a common policy coming on 14 June, when the EEC Council of Energy ministers meets, more worried voices have added a note to the chorus of concern that normally prevails.

It comes from the House of Lords, whose Select Committee on the European Communities is one body in Britain that seeks actually to dissect the stream of proposals and consultative documents emanating from Brussels. Last week the committee released the latest example of its valuable work—its 28th report—to coincide with a debate in the House.

Coming from sub-committee F, which deals with energy, transport and research, the report examines three energy documents prepared by the Commission for the Council of Ministers. One compared EEC objectives set in 1974 with member states' forecasts of their own production and demands; the second warned of the lack of progress towards the aim of greater self-sufficiency; the third focused on the coal industry.

The committee's criticism is almost unsparing. No reliable conclusion can be drawn from the Commission's statistics, it says. There are unexplained inconsistencies and omissions in the figures. Important assumptions are insufficiently discussed, let alone justified. And the figures are not clear and persuasive enough to encourage the Council to take any important decisions, and could even provide an excuse for inaction.

The committee considers that the Community's attention should be concentrated "less on objectives and forecasts and more on the successes and failures of national policies, on the reasons for them, and on research into means of improvement, both technological and social".

One problem may be a surfeit of analysis and of discussion. As Lord Sherfield, a former head of the UK Atomic Energy Authority, commented in debate last week: "While the clock ticks it is difficult to find much that is new to say about the problem until something is actually done about it".

Chris Sherwell

IN BRIEF

OTS delay

Last week it was announced that the launch of the European Space Agency's (ESA) orbital test satellite (OTS), designed for experiments in communications, would not go ahead as scheduled next month because of damage to the American Delta 3914 launch vehicle. In April, ESA's geostationary scientific satellite, Geos, was thrown into a wrong orbit because the Delta 2914 rocket which launched it failed to separate according to plan.

The launch of OTS had already been delayed by the enquiry into the mishap over Geos. The damage to the Delta 3914 occurred when one of the nine solid fuel booster rockets attached to the launcher base fell off, damaging the rocket's first stage. The rescheduled launch date is 8 September; the Meteosat satellite, which was to have been launched on 15 September, has also been rescheduled, for 3 November. ESA decided that it was prefer-

able to delay both satellites by a few months.

OTA director resigns

Emilio Daddario, the first and only director of the Congressional Office of Technology Assessment (OTA), submitted his resignation last week. In a letter to Senator Edward Kennedy, chairman of the joint committee that controls OTA, Daddario noted that the fledgling office has now completed several major studies and he pointed out that he had long expressed a desire to leave as soon as OTA was firmly established. Established four years ago to provide advice to Congress on technical issues, OTA has encountered a difficult problem in giving long term advice to a body whose attention span is largely governed by the two-year election cycle. It has had a mixed reception and last month Kennedy asked the OTA's Independent Advisory Committee to con-

duct a thorough analysis of the office's role and operations. There have been rumours that Kennedy initiated the study and engineered Daddario's resignation as a prelude to taking firm control of OTA. Such rumours were rife when OTA was first established and Kennedy was made chairman of its Congressional board, but they have since proved groundless.

SRC support for AGT

The UK Science Research Council (SRC) is to increase its support for basic research relating to Advanced Ground Transport (AGT). A UK government White Paper released last week says the SRC hopes to spend up to £200,000 a year, concentrated mainly in the universities. This is more than the sum that the SRC has spent altogether over the past three years, but will be less than that spent from all sources over the period 1973-76; this totalled over £1 million.

AN elderly visitor carrying baggage to his bedroom in the usual porterless hotel in modern Britain is likely to suffer at least minor abrasions as he wrestles with the heavily sprung fire doors which obstruct the corridors every few yards. The cost of installing these precautions has meant that hotel charges have risen much more rapidly than inflation alone would have dictated, and many cheaper hotels have closed.

It is right that we should try to make all our activities safe, and new laws may sometimes be required. There have been tragic hotel fires, some buildings are unnecessarily dangerous, but many modifications serve little purpose except to make work for inspectors and builders. The British Health and Safety at Work Act of 1974 contains useful provisions, but its application to laboratories is often governed by dogma rather than commonsense. Precautions, costly in time and money, are taken against the most unlikely catastrophes. Little research has been done to identify the probable dangers in different types of laboratory, where quite different work is done. Our Research Councils must be spending more than £2 million a year, out of their meagre funds, on 'safety'.

This is all part of the 'nanny' to which we are increasingly subjected. We see those who spend their holidays rockclimbing or even in that most dangerous of sports—motorcycling—insisting on following quite different rules when at work. The various admirable and tough outdoor

activities for young people described in his broadcast by the Prince of Wales, and to be supported by the Queen's Jubilee Appeal, will surely

Dangers of safety**KENNETH MELLANBY**

be regulated out of existence.

I find most ludicrous the proposals to set up working parties to draft codes of practice for field work. Field work covers many different activities, some of which may be dangerous, and where obvious and well established precautions should be observed. But for the ecologist it is seldom more hazardous than a gentle country walk to observe birds or to pick wild flowers. Those of us who have done this sort of work should be grateful that someone actually

paid us, for many of our less fortunate friends do these things, possibly less systematically, when on holiday. I expect the code will tell us to change our socks if they get damp, and to wrap up well in cold weather. It is unlikely that any joker will be able to produce 'spoof' regulations which will be more absurd than those to be promulgated by the authorities.

We avoided this nonsense in the past because most field work was done almost entirely by responsible scientists themselves, walking on their own feet and observing with their own eyes. Today there is a growing tendency for scientists to remain indoors in their 'offices' and send assistants, admirable workers no doubt, but not personally committed to the investigation, to do the field work. The results of this practice are often, scientifically, disappointing, and it is understandable that the assistants' trade unions should be obsessional about their safety particularly when this increases opportunities for employment.

However, even the best schemes may have unfortunate results. On what was, by coincidence, the first day of European Farm Safety Week an estate worker drove his tractor a little too quickly over a 'sleeping policeman' (a ramp to slow traffic and prevent accidents). He bounced into the air, and hit his head on the roof of his newly-fixed safety cab, so that he had to be taken to hospital to have his scalp stitched. Too many safety precautions can be jolly dangerous.

An induced birth for the Solar System?

from M. G. Edmunds

DID the Solar System, like the Universe, begin with a bang? The idea that the supernova explosion of a star initiated the formation of the Solar System has recently been re-explored by A. G. W. Cameron and J. W. Truran (*Icarus* **30**, 447; 1977). The model they discuss may also have interesting consequences in deciding what astrophysical objects liberate significant amounts of elements formed during intense neutron irradiation.

The motivation for their renewed interest is an attempt to account for certain radioactive isotope abundance ratios in the early Solar System, as determined from chemical analyses of meteorites. Particularly important is the unusually high abundance of ^{26}Mg found in aluminium rich minerals in the Allende meteorite by T. Lee, D. A. Papanastassiou and G. J. Wasserburg (*Astrophys. J. Lett.* **211**, L107; 1977). The high magnesium isotope abundance implies that its rapidly-decaying progenitor ^{26}Al had been produced not more than a few million years before the condensation of solid bodies in the Solar System. The extreme temperature and pressure conditions of the supernova explosion of a massive star are the site of synthesis of heavy elements. Cameron and Truran therefore argue, since the unrelated chance occurrence of a supernova just before the Solar System formed is unlikely, that the aluminium synthesising supernova must have induced the formation. A shock wave from the supernova explosion passes through the interstellar medium, and this extra pressure on a cool region of somewhat higher density than average, might be sufficient to drive the region into a state of gravitational collapse. This collapsing cloud would then form the solar nebula out of which the Sun and planets formed. Nuclei in the expanding supernova remnant would mix with the cloud material, and by considering isotope ratios, Truran and Cameron estimate (with a large uncertainty) that perhaps 2% of the heavy elements—anything

from carbon onwards—in the Solar System came from the nucleosynthesis zones of the triggering supernova.

The supernova material could be delivered in either gaseous or solid form. Cameron now accepts that solid grains may well condense out of the synthesised heavy elements as the remnant expands and cools. Thus the radioactive nuclei could be incorporated into grains and directly transported, with their products as they decay, into the Solar System material. Subsequent heating of the grains during or after their incorporation into larger solid bodies may well have caused some chemical differentiation and loss of individuality, so that the supernova grains may not be identifiable with particular inclusions in the meteorite. Lee *et al.* give evidence that the inclusions containing high ^{26}Mg must have crystallised when both freshly synthesised ^{26}Al and older material were present, implying that the synthesis must have occurred only shortly before the solidification of the meteorite. Although the ^{26}Al could have become incorporated into grains, the grains must have been freshly made and then melted during or after meteorite formation. The mineral evidence seems to make it unlikely that the ^{26}Mg could have been brought in by old supernova grains long after its production by decay of ^{26}Al , and then directly incorporated as single grain inclusions. Production of ^{26}Al by processes other than supernova synthesis is unlikely, since those which have been proposed predict other isotopic anomalies which are not observed.

Apart from triggering the collapse of the protosolar cloud, the influence of the supernova on the formation of the planets would also be felt in the effect of decay of ^{26}Al as a heat source. Lee *et al.* suggest that the cores of any solid bodies greater than a few kilometres in radius would be melted while the aluminium was still radioactive.

Having a supernova just before the

Solar System formation is not without its embarrassments, since the model requires a revision of earlier ideas on the use of some other isotope ratios as indicators of the time elapsed between formation and the last nucleosynthetic event which contributed material. For example, it is assumed that ^{127}I and ^{129}I are produced in the r-process, in which nuclei capture neutrons in a flux strong enough to give insufficient time for β -decay of the intermediate product nuclei before the addition of the next neutron. In this process ^{129}I and ^{127}I should be produced in about equal amounts. Now ^{129}I is unstable, and the $^{129}\text{I}/^{127}\text{I}$ ratio at the formation of solid bodies in the Solar System used to be used as an indicator of how long the ^{129}I had been decaying since it was produced in an r-process event. The experimental abundance ratio of 10^{-4} implied that the last ^{129}I was synthesised as long as 10^8 years before solidification, obviously long before the ^{26}Al synthesis. This implies that the event which made the ^{26}Al could have released very little r-process material to the interstellar medium. Truran and Cameron propose an alternative in suggesting that all the ^{129}I observed in the Solar System was synthesised in the ^{26}Al -producing event, but by a process involving slow neutron capture to reduce the production ratio by two orders of magnitude. If 2% of the supernova material were incorporated in the Solar System, this would then give the experimental abundance ratio.

This removes the constraint that the last event which contributed r-process nuclei to the Solar System occurred about 10^8 years before formation. It could then have occurred much longer before, since it is no longer required to synthesise the ^{129}I . A similar argument applies for ^{244}Pu . The attraction claimed by the authors is that the ejection of r-process material from

M. R. Edmunds is in the Department of Applied Mathematics and Astronomy at University College, Cardiff.

supernovae can now be regarded as a very rare event. This is important in considerations of the removal of r-process elements from where they are formed near the core of a supernova, before they get trapped in a condensed neutron star or black hole remnant. The most plausible mechanism invokes perturbation of the supernova structure by strong magnetic fields during the collapse of the core. The difficulty is that magnetohydrodynamic calculations indicate that a very large amount of r-process material must inevitably be liberated, and if this occurred in every supernova then the Galaxy would be inundated with far too many r-process nuclei. The previous argument against this mechanism was that, since by a 'Cosmological Principle' the Earth is supposed to occupy no special

position in the Galaxy, it was unlikely that a rare r-process event occurred not very long before formation. This can be relaxed, since there is now no time constraint on when the last r-process contributing event occurred.

The idea that the Solar System origin was induced by a supernova shock wave is not likely to prove unpalatable, since a similar mechanism of cloud collapse induction is believed to cause the formation of bright massive stars in the spiral arms of the Galaxy as the result of the passage of a propagating density wave in the interstellar medium. Nucleosynthesis and Solar System-formation theorists may be rather more reluctant to throw away their useful, but perhaps misleading, timescales previously derived from some of the isotopic ratios. □

Optimal life-history strategies

from Robert M. May

THE idea that an organism's life-history strategy—its patterns of mortality, fecundity and parental care—depends on its physical environment and on its interactions with other organisms dates

back at least to Darwin and Wallace.

Stimulus for a more quantitative approach to the subject came from the work of people such as Deevey (*Q. Rev. Biol.* 22, 283; 1947) and Cole

(*Q. Rev. Biol.* 29, 103; 1954). On the empirical front, Deevey showed how data from natural populations of animals could be used to construct actuarial tables of age-specific survivorship and fecundity, similar to those constructed by insurance companies for human populations. On the theoretical front, Cole made the remark, which at first glance may appear paradoxical, that a population of immortal organisms, each of which produces N offspring each year, has the same growth rate as a population of organisms of which each lives for one year and then dies after producing $N+1$ offspring. The proof of this result, and its generalisation to somewhat more realistic situations, is trivial (although the simplicity is often concealed in thickets of algebra). So long as the survival probability is independent of age, and all organisms reproduce each year, then adults and juveniles have the same potential for future reproduction and 1 adult plus N offspring is reproductively equivalent to $N+1$ offspring. By extension of this argument, if the probability of a juvenile surviving the first year of life is smaller than the adult survival probability by a factor p , then $1/p$ additional offspring are required if the 'annual' life-history strategy is to have the same population growth rate as the 'perennial' one.

More recent studies have emphasised that the number of offspring, and their chances of surviving to maturity, depend on the amount of parental investment (for example, on the number and size of eggs, and on the amount of care, if any, given to offspring), and that this in turn influences the parent's survival probability. To quote one of a multitude of examples, Loschiavo (*Canad. Ent.* 100, 86; 1968) has demonstrated an almost inversely linear relation between the number of eggs laid and the longevity of the beetle *Trogoderma parvum*. Stearns (*Q. Rev. Biol.* 51, 3; 1976) catalogues other examples. Thus in any attempt to calculate optimum life-history strategies for particular environmental circumstances, it must be acknowledged that age-specific mortality and fecundity schedules are not independent, but are intertwined in a complex way; the trade-off between reproduction and 'personal growth' made by an adult in any one year will affect its probability of surviving that year, and thereby influence the possible trade-offs in all future years.

An excellent review of most work in this area up to 1975 has been given by Stearns. Schaffer (*Ecology* 55, 291;

Fig. 1 The outcome of two different strategies for allocating resources in a hypothetical animal, the block-fish. *a*, Mutation 1 in which summer productivity (two blocks) is entirely allocated to reproduction; *b*, Mutation 2 in which one block of summer productivity is allocated to reproduction and one block to growth and, hence, to adult survival. (After Southwood, *op. cit.*)

Robert M. May is the Class of 1877 Professor of Zoology in Princeton University.

1974; *Am. Nat.* **108**, 783; 1974), Goodman (*Am. Nat.* **108**, 247; 1974) and others have given mathematical discussions, and Pianka and Parker (*Am. Nat.* **109**, 453; 1975) have subsequently given a graphical analysis of the way optimal strategies are moulded by trade-offs between present and discounted future reproduction. A discussion which is particularly simple and clear, yet which retains all the biological essentials, is due to Southwood (Ch. 3 in *Theoretical Ecology*, Blackwells (UK) and Saunders (USA), 1976). He invokes an imaginary animal, the parthenogenetic block-fish, which has a productivity of two blocks each summer and one block each winter. The two summer blocks can be added to the fish itself, or used in reproduction, in any proportion (any fish that does not add to itself dies); the one winter block is necessarily added to the fish itself. What is the optimal life-history strategy for the block-fish? Obviously there is no unique answer, but rather it depends on the environmental setting. Figure 1 illustrates the genealogy of two mutant strains of the block-fish: mutation 1 puts all its summer productivity into reproduction; mutation 2 puts only half its summer productivity into reproduction. If half the juvenile one-block fish are killed by predators each year, mutation 2 does better. Conversely, if the carrying capacity of the fish's environment is limited to a total of eight blocks, mutation 1 is represented at the end of three years by many more individuals, and is better placed to "bounce back" from adverse environmental fluctuations. Other assumptions could clearly be explored; for example, block-fish over a certain size could exploit additional resources, or mortality could be higher or lower for larger block-fish, or the environmental carrying capacity could be subject to random variations.

The insights provided by his imaginary block-fish, and by earlier work, enable Southwood to draw together a great deal of information about the trend in life-history strategies manifested by animals and plants, and particularly by birds and by insects. It would be nice to have more experiments aimed at explicit determination of the trade-off between present reproduction *versus* survival and future reproduction. Some such work exists, mainly directed at the relative investment between reproductive and vegetative parts in plants (see for example, Harper & Ogden *J. Ecol.* **58**, 681; 1970; Gadgil & Solbrig *Am. Nat.* **106**, 14; 1972), but by and large it is easier to issue hortatory calls for such experiments than to do them.

Of particular interest is the study of

the optimal reproductive strategy for eusocial insects given by Macevicz and Oster in the new journal *Behavioural Ecology and Sociobiology* (**1**, 265; 1976). They begin by observing that, for colonies of eusocial insects with an annual life cycle, the optimisation problem is to find the allocation of colony resources that maximises the total number of reproductives produced by the end of the colony cycle. For simplicity, Macevicz and Oster assume only two castes, workers *W* and reproductives *Q*. Differential equations are constructed to describe how the growth in the number of workers and of reproductives at any given time depends on *W* and *Q* themselves, on the resources *R* gathered by the workers, and on the 'control variable' that measures the fraction of resources devoted to producing workers, rather than reproductives. A third equation relates *R* to the ergonomics of the colony (the time and energy budgets of foragers); such a relation has been developed and compared with data by Oster (*Am. Nat.* **110**, 215; 1976), but Macevicz and Oster are content to use a simple phenomenological equation. Standard techniques from optimal control theory are then used to find the strategy that maximises *Q* at the end of the cycle. Although presented lucidly and unpretentiously, all this is an order of magnitude more sophisti-

cated than previous work on optimal life-history strategies.

The solution, which emerges independent of many of the details, is a so-called 'bang-bang' control policy. In the first phase, the total reproductive effort is directed towards producing workers. Then, at a critical time t_s approximately one generation time before the season ends, the entire effort is thrown into producing reproductives (queens and males). The theoretical optimal control solutions are confronted with data on the wasp *Vespa orientalis* and on the hornet *Polistes fuscatus*. In both cases, the discontinuous 'bang-bang' policy is evident, and theoretical and actual values of t_s agree to within about 1 day. For *V. orientalis*, the observed and predicted number of workers and reproductives are in remarkable agreement over the entire colony cycle; for *P. fuscatus* the agreement is only fair.

Macevicz and Oster point out that discontinuous 'bang-bang' control policies will characterise a wide class of related optimisation problems, and, in particular, that such policies necessarily apply to any colony or population that undergoes exponential growth throughout its cycle. Realistic complications, such as non-linear density-dependent effects or time delays, may or may not lead to smoothly varying control. □

Superfluid helium: untying the tangle

from P. V. E. McClintock

THE celebrated superfluid properties of helium-4 only exhibit themselves while the liquid is being treated fairly gently. Up to a certain critical velocity it can flow through a tube in a completely frictionless manner, without needing to be pushed to keep it moving. At higher speeds, however, this simple superfluid behaviour disappears abruptly as turbulence is generated and a corresponding flow resistance appears. The resultant turbulent state of the superfluid is of considerable intrinsic interest, particularly in view of the quantum properties of the liquid. A recent paper in *Physical Review Letters* (**38**, 551; 1977) by K. W. Schwarz of the IBM Research Centre at Yorktown Heights represents the first serious attempt to tackle the dynamics of the turbulence and, judging by comparisons with experimental data, his theory seems to be remarkably successful.

Surprisingly, turbulence in superfluid helium is very much simpler than in other liquids, mainly because the so-called quantisation of circulation means that the turbulence takes the

form of a mass of vortex lines such that any element of vortex line is identical to any other. Each vortex line consists of a narrow core region, which may be imagined as being hollow, surrounded by superfluid which circulates rapidly close to the core and more slowly at large distances from it. Turbulence consists, then, of a seemingly random tangle of these vortex lines in constant relative motion because each element of line exists in the flow fields around all the other lines. The situation has been likened to a mass of moving spaghetti, or a basket of writhing snakes (although free ends would be unstable, so one is really obliged to imagine spaghetti in tangled rings, or snakes which have swallowed their tails). These analogies must be treated with caution, however, because in reality the spacing between neighbouring segments of line is very much greater than would seem to be implied.

Most of our present understanding

P. V. E. McClintock is a lecturer in the Department of Physics at the University of Lancaster.

of the turbulent state is due to the work of W. F. Vinen (*Proc. R. Soc. A* **240**, 114, 128, 1957; *A* **242**, 493, 1957; *A* **243**, 400, 1958). He envisaged that, in the equilibrium situation, the rate at which new vortex line was being created by 'frictional' effects would be exactly balanced by an annihilation mechanism whereby vortex line would be being continually destroyed. His theory, which was based largely on dimensional considerations, had nothing to say about the details of either the creation or the annihilation mechanisms, so that there has been a continuing debate about what might actually be going on in the liquid. One school of thought held that the lines were annihilated when, in the course of their random movement, they crossed each other, while others believed that such a crossing would be able to occur without the lines even 'noticing' each other, let alone being an event which would lead to their mutual destruction. Sitton and Moss (*Phys. Rev. Lett.* **29**, 542; 1972) suggested that the annihilation mechanism arose from the magnus force which tends to drive together parallel sections of line with opposite circulation; but this idea was not supported by subsequent experimental work by Ashton and Northby (*Phys. Rev. Lett.* **30**, 1119; 1973). The situation has remained obscure.

There have, in fact, been growing indications of the inadequacy of the Vinen model, arising mainly through experiments in which charged ions are used to probe the movements of the tangle of vortex lines. In one such experiment, Ashton and Northby (*Phys. Rev. Lett.* **35**, 1714; 1975) were able to demonstrate that the tangle was not moving at the same speed as the superfluid (in fact, it was travelling in the opposite direction), thus contradicting one of the central assumptions of Vinen's theory, that the tangle of lines must be isotropic. It was clear, therefore, that a more sophisticated approach was needed.

What Schwarz has now attempted is to take some explicit account of the actual way in which the lines move relative to each other and to distant parts of themselves: a daunting task which has, of course, required a statistical approach. His central equation, describing the rate of change in the length of line per unit volume of liquid, is extremely complicated, but contains no adjustable parameters. An interesting feature is that it seems to imply, quite contrary to the premises of earlier theories, that the most important velocity is not that of the random inter-line movements, but is that of a segment of a line relative to other segments of the same line. The solution

of this equation has necessitated the use of numerical methods. It turns out that, for any given temperature and flow velocity of the liquid, a forward integration in time leads to the same steady-state distribution of vortex line, regardless of the assumed initial distribution of lines: apparent confirmation that the theory is at least self-consistent. More importantly, it seems to be in remarkably good agreement with experiments. Contrary to the Vinen theory, it predicts that there will indeed be a relative velocity between the vortex tangle and the superfluid, with the tangle tending to move in the same direction as the thermal excitations in the liquid. Furthermore, both the magnitude of this velocity and its temperature dependence are in good agreement with the measurements of Ashton and Northby. The predicted line density turns out to be in satisfactory agreement with Vinen's original measurements; and, again, the calculated temperature dependence is as it should be.

These results are extremely encouraging. It will be interesting to see whether the model will be able to deal equally successfully with critical velocities for the onset of turbulence, and with the transient situations which occur when turbulence is building up or dying away in the superfluid. No doubt there will be a brisk renewal of interest by experimenters, now that there is a seemingly satisfactory theory waiting to be verified or contradicted.

What can artificial intelligence offer psychology?

from Tim O'Shea

A meeting entitled 'What can artificial intelligence offer to psychology' was held at the University of Bristol on 14-15 April, 1977. It was organised by Richard Young (University of Edinburgh) and Tony Conway (University of Bristol) for the Society for the Study of Artificial Intelligence and Simulation of Behaviour (AISB).

ARTIFICIAL Intelligence is an investigation into the principles underlying actual and possible forms of intelligent behaviour. In part this objective is shared with psychology which is, however, concerned with human and animal behaviour. The methodology of artificial intelligence, unlike that of psychology, is based not on experimentation with people and animals, but

on the design, implementation and analysis of computer programs which exhibit intelligent behaviour. The aim of the meeting was to examine the relevance and applicability of this methodology to psychological research. Most of the speakers were active research workers in artificial intelligence but many of the other participants were cognitive psychologists. The work presented ranged in application from H. C. Longuet-Higgins' (University of Sussex) program for the perception of melodies to S. Weir's (University of Edinburgh) account of therapeutic work carried out with an autistic child.

Opening the meeting R. L. Gregory (University of Bristol) used the variety of types of intelligent behaviour as the basis for criticising attempts to measure intelligence by a single numerical IQ score. He proposed a distinction between 'design intelligence' (a pre-existing or 'wired-in' intelligent solution to a problem) and 'processing intelligence' (the generation *de novo* of intelligent solutions) and argued that artificial intelligence has made explicit the large amount of 'processing intelligence' necessary for perception and simple skills. He also suggested that the construction of robots with restricted 'design intelligence' provides a way of examining the effective use of limited data.

A large proportion of the talks described fully or partially implemented computer programs. These papers were probably the most useful, as the research methods of artificial intelligence and the current state of the art were made explicit through the discussion of the actual programs. The thesis that artificial intelligence should be regarded as theoretical psychology was cogently put by Longuet-Higgins. He argued that artificial intelligence provides psychologists with an appropriate descriptive medium for the expression of theories. These take the form of computational mechanisms which can be used to specify the complex interacting processes necessary for intelligence. This view of artificial intelligence as theoretical psychology was strongly supported by R. Schank (Yale University) in his discussion of language comprehension. Schank argued that process models are essential in any account of linguistic phenomena and that such models could best be realised as computer programs. He illustrated his argument with an account of a computer program which takes as input stories set in restaurants. It uses 'scripts' of the expected sequences of

Tim O'Shea is a Research Associate in the Department of Artificial Intelligence at the University of Edinburgh and Editor of the AISB Newsletter.

actions in restaurants to 'understand' such a story. The extent of its understanding is demonstrated by its ability to answer English questions about the story, including making inferences about events that must have occurred between the incidents specifically mentioned.

Many speakers argued that the construction of computer models which exhibit intelligent behaviour requires the use of knowledge from a variety of different domains. For example, phonetics, syntax, semantics and pragmatics are all necessary for the synthesis of intelligible speech. This point was nicely illustrated by S. Isard (University of Sussex). He is working on the problem of determining the 'right' intonation contour for a given English sentence taking into account the intended meaning and the context in which it is spoken. Consider the sentence 'I bought a boat and *that* sank'. A different intonation pattern is applied in the case where the speaker assumes it is known that his first boat blew up, from the pattern applied where the speaker is trying to correct the mistaken impression that it was his first boat that sank. Isard described a program which he is developing to explain how the differing contexts in which a sentence is uttered give rise to different intonation patterns. The program produces spoken English generated by a speech synthesiser. (The tape-recordings of the generated speech he played had an oddly Scandinavian lilt.) One argument for the development and specification of psychological theories as computer programs was that they can then be run on a computer and their consequences seen in a clear form. Isard illustrated this by describing various experimental changes he had made to the components of his program and discussing the effects these changes had had on the intonation of the generated speech. He concluded his account by observing with disarming equanimity that 'parts of my program are starting to interact in ways that are making me uncomfortable'.

How best to organise such complex programs remains an open question. A. Sloman (University of Sussex) argued that there was a need to deploy the different components of an intelligent program concurrently rather than sequentially. Sloman illustrated his argument by a description of the interactions between the different levels of a program which interprets visual scenes composed of overlapping letters. Such arguments for the need for parallel processing in computer models of intelligent behaviour were responded to with enthusiasm by some of the psychologists present. But on the whole the psychologists were sceptical of compu-

tational analyses of cognitive functions which were not based on any concrete computer program. The main criticism ironically enough was one often levelled at psychological theories, namely a lack of rigour together with a resulting absence of predictive power. P. J. Hayes (University of Essex) argued that the difference between theories in artificial intelligence and those in psychology is that the former must be implemented as computer programs to be viable, while the latter must make experimentally testable predictions. J. M. Brady and R. Bornat (University of Essex) asserted that the main strength of computer programs as models of cognitive processes was that they were precise enough to be refuted. They contrasted such programs with contemporary models in cognitive psychology which they suggested are couched in computational terms but are not, in practice, implementable as computer programs. D. A. Allport (University of Reading) gave examples of general organisational principles such as heterarchy and debugging which might be applicable in psychological explanations. However he argued that the main benefit of artificial intelligence to psychology so far lies in the carefully detailed analysis motivated by the demands of developing computational descriptions rather than in the application of general principles. He criticised workers in artificial intelligence for paying insufficient attention to known psychological phenomena. While this criticism certainly applies to some of the work presented it could not, for example, be applied to G. Kiss's (University of Warwick) analysis of the computational complexity of some simple cognitive processing tasks. This analysis was directly applied to experimental findings on memory span and other results. Nor could this criticism be applied to the style of development espoused by G. Luger (University of Edinburgh) for a computer program which solves 'A' level mechanics problems. Luger repeatedly emphasised the necessity for analysing protocols of human subjects as a source of design ideas for programs intended to have natural language understanding and problem solving capabilities. Allport also pointed out that much artificial intelligence work is judged against the intuitive sufficiency of the mechanisms used. The validity of this objection was made clear by the ambiguous and easy response of many of the speakers when questioned on their views of computer programs which performed some task requiring intelligence but did not make the same errors as humans.

Despite the gladiatorial format of the meeting there was a surprising degree of consensus between the psy-

chologists and the workers in artificial intelligence. This was particularly apparent during M. Eisenstadt's (Open University) account of a new course in cognitive psychology. This course is based on the artificial intelligence view that representation and symbolic processing are central to the specification of cognitive functions. No one seriously questioned that artificial intelligence is in principle useful to psychology and there was general agreement that there is a large gap between current experimental work in psychology and the construction of computer programs. The difficulty of making empirically testable predictions of human performance (from the execution of computer programs) was repeatedly stressed. In the long term the most valuable contribution of artificial intelligence to psychology may be to liberate it from a methodology based on a quest for simple explanations relating quantitative variables. This search for simple mechanisms underlying human behaviour is characterised by the collection of a mass of experimental data in the absence of precise theories about the underlying cognitive functions. Artificial Intelligence offers a methodology for the development and elaboration of symbolic representations for the processes underlying intelligent behaviour. □

Probing satellite DNA

from Gabriel Dover

THE point has been reached in the study of highly repetitious (satellite) DNA of higher organisms where earlier plausible generalities can no longer significantly advance our understanding of the origin and function of this species of DNA. These generalities were usually based on correlations between aspects of chromosome behaviour (often during meiosis) and the composition, amount and chromosomal location of heterochromatin (or satellite DNA).

Early studies showed that the majority of satellite DNAs are highly homogeneous in sequence and some can differ from each other (whether in the same or different species) by relatively few base changes despite the lapse of long periods of evolutionary time. They are concentrated in sections of the chromosome adjacent to the centromeres and telomeres which are involved in chromosome positioning

Gabriel Dover is a lecturer in the Department of Genetics in the University of Cambridge.

during the cell division cycle. Furthermore there is no concomitant replication of satellite DNA in specialised cells having polytene chromosomes.

These almost diagnostic features of satellite DNA have led to much current interest in the molecular mechanisms responsible for the generation and maintenance of homogeneity of sequence and in its biological role: a situation analogous to the conserved and non-conserved sequences, within and between species, of multigene families and their spacers.

Some answers to these questions can be gained from studies that probe more extensively the sequence organisation of satellites, the finer patterns of satellite distribution on the chromosomes, and the extent of satellite sequence homologies in species of known phylogenetic relatedness.

Important new data obtained by a combination of these approaches is reported on the satellite DNAs of *Drosophila melanogaster* (Brutlag *et al. J. molec. Biol.* **112**, 31; 1977; Shen & Hearst *J. molec. Biol.* **112**, 495; 1977). There are four major satellites in this species (Peacock *et al. Cold Spring Harbor Symp. quant. Biol.* **38**, 405; 1973; Endow *et al. J. molec. Biol.* **96**, 665; 1975) ranging from 2.6–5.3% of total DNA (equivalent to 4–8 million bases each) that are located at the chromocentres of salivary gland cells. If satellites are the basis for the differences in behaviour of pairs of homologous chromosomes it might not be unexpected to find a pattern of distribution of these four satellites that is chromosome specific, and in addition to locate sequence variants of individual satellites on individual chromosomes. Brutlag *et al.* after determination of the composition and properties of major and minor satellite peaks (resolved in antibiotic-CsCl gradients), have demonstrated that there is an upper limit of between 8–10 chromosomal sites for each block of satellite (of average size 750,000 bases) and that these blocks are predominantly interspersed with each other. Their argument is based on the interpretation that the minor peaks represent linkage molecules at the boundaries of contiguously covalently linked blocks and have buoyant densities commensurate with a dual satellite composition. Hybridisation of homogeneous pure satellites to a minor peak associated with satellite IV ($\rho = 1.705 \text{ g cm}^{-3}$) shows that it contains sequences of three flanking satellites (1.705, 1.686 and 1.672), in conjunction with some main-band DNA.

Although there remain several, as yet, untested minor satellites, this interpretation is secure when considered in conjunction with *in situ* hybridisation experiments at CSIRO (Peacock *et al.*,

in preparation), that have revealed chromosome-specific patterns of interspersed blocks of satellite making up the heterochromatin around mitotic centromeres.

The existence of sequence variants within a satellite can be demonstrated with the use of restriction endonucleases as probes to examine the range and types of long periodicities that may overlay the basic short repeating unit. If sites, susceptible to attack by a particular endonuclease, are regularly spaced throughout a block of satellite DNA then the DNA fragments produced after enzyme digestion will be of a uniform size indicative of this high-order spacing. Satellite IV has hitherto proved particularly resistant to a number of restriction enzymes and it has not been possible to detect higher-order periodicities of the sort reported in satellites of other organisms (Southern *J. molec. Biol.* **94**, 51, 1975; Botchan *Nature* **251**, 288; 1974) and in satellite III of *D. melanogaster* (Manteuil *et al. Cell* **5**, 413; 1975). However Endow (in the press) has recently succeeded in cutting it with *Mbo*II, confirming its repeating pentamer purine sequence of (AGAAG)_n and its high (95%) conservation of sequence.

The novel use of 4,5',8-trimethylpsoralen (trioxsalen) on satellite IV by Shen and Hearst in conjunction with denaturation microscopy has revealed a regular distribution of cross-linkable pyrimidine sites at intervals of approximately 250 base pairs and brings this satellite firmly into line with those of mouse, guinea-pig, calf and green monkey in its organisation. This is not only an important step forward in the application of a new method for probing satellite sequence organisation, but also raises intriguing questions concerning the universality of higher-order repeats, the mechanism of their evolution and maintenance and, naturally, their biological role. Recent data by Zachau and his colleagues at Munich on the organisation of mouse, guinea-pig and African green monkey satellite DNAs (Horz & Zachau *Eur. J. Biochem.* **73**, 383; 1977; Altenburger *et al. Eur. J. Biochem.* **73**, 393; 1977; Fittler *Eur. J. Biochem.* **74**, 343; 1977) indicates that satellite evolution is even more complex than at first realised. The pattern of fragment sizes produced after successive- and co-digestions of satellite DNA with several restriction enzymes revealed the existence of satellite sequences (segments) within the block of satellite DNA that are variants of a common ancestral sequence. This is with respect to the organisation of higher periodicity, in that sites sensitive to different restriction enzymes are clustered in different parts of the satellite block.

The stage is now set to investigate the possibility of equivalent segments (sequence variants) in the satellites of *Drosophila* and to relate this to the new data of Brutlag *et al.* and Shen *et al.* Sequence variants of a satellite could reside either on different homologous chromosomes (thus reinforcing the chromosome differences in the patterns of satellite distribution) or in other species that are closely related to *melanogaster* and that have some satellites in common. Such comparisons, currently underway by Sederoff and his coworkers in Oregon; at Canberra (Australia) by Peacock's group; and at Cambridge, UK on the *melanogaster* species group, might reveal something of the order of events in the evolution of satellite DNAs that has led to their contemporary composition and distribution both within and between closely related genomes and resolve some of the intriguing problems associated with this enigmatic species of DNA. □

A hundred years ago

"SUMMER Schools" are becoming a regular institution in America, and no more pleasant way could be devised of combining the *dulce* and the *utile* than that of a proposed aquatic summer school of natural history, which, under the direction of Prof. Theodore B. Comstock, of Cornell University, expects to charter a large steamer, and spend the summer around the shores of Lake Superior in the study of the geology and natural history of that region. The steamer will accommodate from seventy-five to one hundred passengers, to be made up of students and professors. Regular instruction will be given in the form of lectures during the voyage, and every facility afforded by the examination of mining localities and the like. The vessel will probably start from Cleveland or Detroit on July 7, and proceed thence to Lake Superior, making its full circumnavigation. The coast of Georgian Bay, on Lake Huron, will be investigated on the return voyage. The expense will probably amount to about 125 dollars for each person. In addition to the aquatic summer school mentioned above, Harvard University announces two special summer courses of instruction, one in zoology and the other in geology.

A history of geodynamic evolution of the Mediterranean leading to the salinity crisis is outlined, based on the 'desiccated deep-basin model'. An accurate portrayal of the crisis is presented, based on data from new drilling and studies of on-land geology.

THE discovery of the Mediterranean Evaporite by the drilling from Glomar Challenger in 1970 proved that salt exists under deep-sea floor¹, and demonstrated that giant salt deposits could have been formed within a relatively short geological time². The almost synchronous onset and termination of the Mediterranean salinity crisis implies catastrophic changes of environments in a region over two and half million square kilometers in extent. This fact did much to throw doubts on Lyell's substantive uniformitarianism³.

The significance of the Deep Sea Drilling Project (DSDP) discovery was, however, shadowed by controversies. That the Mediterranean Evaporite is Messinian (Late Miocene) in age seemed to be just about the only consensus after the Leg 13 drilling. Even the shipboard scientific staff could not reach an agreement on the genesis of this unusual formation. Chapter 43 of the Leg 13 cruise report presenting the desiccated deep-basin model (ref. 4) was authored by K. J. Hsü, Maria Cita, and W. F. B. Ryan because they were the only members of the shipboard staff totally convinced of its plausibility. Alternative interpretations were given by other shipboard staff in the Initial Cruise Reports and later in other publications^{5,6}. The reactions of the scientific community to the desiccated deep-basin model were also divergent. Favourable commentaries were not rare. On the other hand, many critiques were sceptical, or downright hostile.

The importance of clarifying the question of the Messinian salinity crisis did not escape the attention of the JOIDES organisations. A second cruise to the Mediterranean took place in 1975. We are glad to report that we reached a near-consensus on the previously controversial question of the origin of the Mediterranean Evaporite. This article is not a perfunctory report requiring a co-authorship by the shipboard scientific staff. It is a

unanimous opinion written by the senior author for ten co-authors, who represent all but two of the shipboard scientific staff during the Leg 42A cruise.

The Miocene Mediterranean

Whereas there seemed to be general agreement that the Messinian (Late Miocene) evaporites were deposited in shallow water conditions, controversy revolved around the basin depths at times of evaporite deposition⁷. The crux of the matter is the genesis of the Mediterranean basins. When did the Mediterranean basins form? In the Early and Middle Miocene before the Messinian salinity crisis⁸? In the Pliocene shortly after the salinity crisis⁹? Or "did the main phase of subsidence occur rather abruptly during the Pleistocene and Holocene"¹⁰. Syntheses of regional tectonic data led to the conclusion that the deep basins of the Mediterranean have evolved to a stage quite similar to their present configuration before the Late Miocene when the salinity crisis began^{4,11-14}. Of the five major Mediterranean basins, the Levantine and Ionian basins may be relic Tethys of Mesozoic age; The Balearic and Tyrrhenian were formed during the Early and Middle Miocene, after the culmination of the Alpine orogeny. Perhaps only the Aegean has undergone significant Plio-Quaternary subsidence.

Deep-sea drilling during the Leg 42A has unearthed convincing evidence that deep Mediterranean basins were in existence before the Messinian. Drilling at Site 372 (Fig. 1) indicated that the Balearic Basin was formed by rifting during the latest Oligocene or earliest Miocene time. Palaeobathymetric analyses on the basis of benthonic foraminifera estimated that this part of the Balearic margin was at least 900 m deep during the Early Miocene (Burdigalian) time. The water depth reached in excess of 1,200 m during the late Burdigalian and subsided gradually to a depth more than 1,500 m before the Middle Miocene ended¹⁵.

The pre-Messinian sequence at Site 372 is mainly hemipelagic, similar to the sediments deposited there today. The planktic and benthic faunas and floras are fully open marine. Aside from benthic foraminifera, psychrospheric ostracods also occur in some Early and Middle

Fig. 1 Drill sites of DSDP Leg 42A.

Miocene cores, indicating water-depths in excess of 1000 m (ref. 16).

Drilling results at Site 373 seamount indicated that a deep Tyrrhenian Basin was also in existence during the Messinian. Palaeotemperature estimated for the submarine cementation (by calcite) of the early Pliocene pillow breccias at this site is estimated by isotopic evidence to be 6–8 °C (ref. 17). Such a low temperature implies that the volcanic seamount was deeply submerged then, only a short time after the salinity crisis.

We penetrated beyond the Messinian at Site 375 west of Cyprus in the Levantine Basin. As in Hole 372, the pre-Messinian sequence at this eastern Mediterranean site is also mainly hemipelagic. Palaeobathymetric analyses indicate that the Levantine Sea was a deep, open sea during the Miocene before the Messinian salinity crisis¹⁵.

Events leading to the salinity crisis

Geological reconstructions indicate the presence of an equatorial ocean, which separated Europe from Africa during the Jurassic and Cretaceous and the ocean was named Tethys^{14,18}. The connection between the Atlantic and the Indo-Pacific was maintained through a shallow seaway after the joining of the two continents in late Cretaceous¹⁹. This shelf sea started to disappear during the Burdigalian (late Early Miocene). This was one of the major palaeobiogeographical events of the Tertiary; it was during this period that "the present pattern of land and sea was established"²⁰. The joining of Europe and Asia permitted the exchange of land fauna between those continents, and started the differentiation of the Indo-Pacific and Atlantic-Mediterranean marine faunas. Whereas the evidence from vertebrate palaeontology indicates the establishment of first intercontinental connection between Eurasia and Africa during the Burdigalian²¹, the micro-palaeontological data suggest that there might have been repeated transgression into the Mediterranean from the Indo-Pacific till Middle Miocene time²² (Fig. 2).

The orogenic movements which fused Eurasia and Africa also raised new mountains in the Taurides, the Hellenides, the Dinarides, and eventually, somewhat later in the Middle or early Late Miocene, the Helvetic Alps. This series of

movements led to a separation of the Mediterranean and an eastern European inland sea, the Paratethys. Stratigraphical and palaeobiogeographical data indicate that the Burdigalian connection between the two seas went through the Peri-alpine Depression north of the Alps^{22,23}. This seaway was eliminated early in Middle Miocene, when the Alps rose and marine waters withdrew from the Molasse trough. A last thread of contact was probably maintained between the Mediterranean (Langhian) and the Paratethys (early Badenian) through an opening in northern Italy and north-western Yugoslavia. The complete separation of the two inland seas took place some 14 to 15 million years ago during the Serravallian (late Middle Miocene). The last Indo-Pacific flooding that invaded the Paratethys later in the Serravallian (14–13 Myr) did not reach the Mediterranean²².

The Middle Miocene separation had two consequences. The Paratethys could no longer receive marine water from the Mediterranean nor could the Mediterranean receive freshwaters from that part of Eurasian rivers which now emptied themselves into the Paratethys. When the connection was open, surplus ions resulted from evaporative excess in the Mediterranean may have found their way to the Paratethys, and were deposited as the lower Middle Miocene salts of the Pannonian and Transylvanian Basins²². After the loss of communication the Mediterranean was deprived not only of much freshwater influx but also of one of its means of the elimination of evaporative waste.

The Mediterranean's last links to the world ocean were the Betic and the Rif Straits. The deep Betic Strait shoaled after the end of the Middle Miocene; no Late Miocene psychrospheric ostracodes were found inside the Mediterranean¹⁶. Yet open marine conditions prevailed in the Mediterranean during the earlier parts of the Late Miocene (Tortonian and early Messinian)²⁴.

The Messinian change from normal marine to an evaporite-forming condition was a sudden event. The palaeobotanical record gives no evidence of an abrupt change in climate. There had been a general trend towards a drier and cooler climate since the Burdigalian, when the Mediterranean was first cut off from the Indian Ocean²⁵. Thus we cannot interpret the change from normal marine to evaporative conditions as a response to climatic factors; the

change had to be related to a final closure of the openings at the west during the latest Miocene. With the isolation and a serious hydrographic deficit, the salinity crisis of the Mediterranean finally became inescapable.

The Messinian salinity crisis

Seismic records suggested a twofold division of the Mediterranean Evaporite²⁶. (1) An Upper Evaporite sequence, with numerous reflectors, up to several hundred metres thick, and consisting of dolomite, gypsum, anhydrite, and some salts. (2) The Main Salt and Lower Evaporite sequence, seismically homogenous salt, up to a thousand metres thick or more, underlain by several evaporite reflectors. The distribution of the Main Salt unit is restricted to the more central part of each of the Mediterranean basins. The distribution of the Upper Evaporite unit is, however, more extensive.

Since drill cores only yielded information on the Upper Evaporite, we depend on land sections for an overview of the Messinian salinity crisis. The onset of the salinity crisis as in Sicily, for example, indicated by the contact of *Calcare di base* on 'Tripoli', signifies a very rapid change from a bathyal environment of hemipelagic sedimentation to a shallow, or subaerial environment of carbonate deposition and diagenesis²⁴.

The history of the early evaporite deposition can be deciphered from a reference to the section of the Cattolica basin, Sicily²⁷. The Lower Evaporite sequence there lies above the Tripoli Formation and includes (1) *Calcare di base*, (2) Cattolica Gypsum, (3) Clastic Gypsum beds, (4) halite and potash salts.

The salts are in general 300–500 m thick. Decima²⁸ divided a 330-m section of salts at Porto Empedocle into four units. The Unit A is a halite with laminae of anhydrite and is 108 m thick. The bromine content of the halite is about 400 p.p.m. The Unit B is well laminated halite, kainite, polyhalite and anhydrite, and is 115 m thick. The bromine content ranges from 200 to 250 p.p.m. except for the uppermost pure halite which contains some 100 p.p.m. Br. The Units C and D overlie the lower salts unconformably. They are 107 m thick and consist of halite, with anhydrite and anhydritic shales. The halite in these upper units has only traces of bromine (10 p.p.m. or less).

The lower salts with their high Br were precipitated from brines derived from evaporated seawater. In contrast the upper salts were recycled. Sedimentological studies²⁹ indicated that the upper salts were deposited in shallow saline environments. On the other hand, the well laminated Unit B, with sequences of cyclic lamination that can be correlated for long distances, were precipitated in a relatively deep subaqueous environment.

The Lower Evaporite is overlain unconformably by a Upper Evaporite of gypsum and marls. A comparison of the submarine Messinian with the Sicily section suggests a similar two-stage evolution of the Messinian salinity crisis in other Mediterranean basins. After an initial desiccation or partial desiccation, the Lower Evaporite was probably precipitated when the supply of brines was sufficiently continuous, to cause the accumulation of thick halite and potash salt deposits on the deepest floor of the Mediterranean basins. Toward the end of the Main Halite deposition, the supply of brine probably ceased because of a complete isolation from the Atlantic. The brine level was drastically drawn down because of evaporative loss. Large areas on the periphery of the salt basins were exposed. Waters from the continent or from local precipitation formed salt creeks, eroding primary salts (for example Units A and B, Porto Empedocle), and depositing secondary salts (for example Units C and D) in the centre of the salt basins. This desiccation period was represented by the widespread unconformity separating the Lower and

the Upper Evaporite units. Rivers cut canyons on the margins of the continents and some of these canyons were eventually flooded by the Upper Evaporite deposits²⁶.

The erosional event was ended by a new inundation of the Mediterranean, when the Mediterranean was probably again filled to the brim. The lower marine marls of Messinian age at DSDP Site 372 (Core 9/2) are the first sediments above the unconformity and they may have been deposited during this intra-Messinian flooding. The subsequent history of the Upper Evaporite sedimentation was probably characterised by periodic influx of marine waters into a largely desiccated deep basin³⁰. A repetition of marine inundation, followed by isolation, and evaporative draw-down led to the accumulation of marls, stromatolitic carbonates, gypsum, anhydrite and salts, in cyclic sequences.

Lago Mare

The geological record of the eastern Mediterranean holes revealed a drastic change in depositional environment during the latest Messinian time before the final Pliocene marine inundation. After the last salt deposition of the Upper Evaporite, the Ionian and Antalya basins were almost totally dried up. Slight changes in the water-budget led to conditions of cyclic sedimentation. The very last Messinian sediments at Sites 374 and 376 are marls, however, deposited in a standing body of water. Isotopic evidence suggests a considerable influx of continental waters to those previously desiccated basins³¹.

Site 376 samples contain an *Ammonia-Cyprideis* fauna, indicative of the euryhaline environment. Similar *Cyprideis* and other euryhaline faunas are present in numerous uppermost Messinian sections on land in both the eastern and western Mediterranean countries. The Mediterranean hosted a series of fresh or brackish water lakes toward the end of the Messinian. We propose that the term *Lago Mare* be used to designate the latest Messinian lake (or oligohaline) environments in the Mediterranean, subsequent to the evaporite-deposition, but before the Pliocene marine sedimentation²⁴.

The change from salt-precipitation in shallow salinas to deposition of marls in *Lago Mare* occurred within a very short time interval probably in less than 100,000 yr. The change implies a radical alteration of the hydrographic budget. There was, however, no drastic climatic change during the Messinian. The environmental change must have been related to a reorganisation of the drainage system in Europe. The sudden appearance of so much fresh or brackish water, together with a typical Paratethyan fauna, probably indicates a sudden inundation of the desiccated Mediterranean by Paratethyan waters from eastern Europe (Fig. 3).

Fig. 2 Middle Miocene (16–18 Myr) Palaeogeography.

Fig. 3 Late Miocene (5.5 Myr) Palaeogeography.

That such an invasion did take place has been speculated by biogeographers on the basis of the occurrence of relic Paratethys faunas (including freshwater fish, molluscs and birds) in isolated areas of circum-Mediterranean land today³². The evidence from Paratethys also indicated that it suddenly lost much of its waters to the Mediterranean in late Neogene³³. In fact, the drainage reorganisation at this time is believed to have resulted in an evaporative excess of the hydrographic budget of the Black Sea, leading to a partial desiccation of that deep Paratethyan basin³⁴.

The *Lago Mare* may have occasionally extended to the western Mediterranean. The *Cyprideis* fauna is present in land sections in Algeria, Spain, Tuscany, and in Sicily³⁴. A brackish water sediment is present in the Balearic Hole 124 within the evaporite sequence and may be equivalent to the lower part of the *Lago Mare* sequence of the eastern Mediterranean. The very last Messinian sediments there below the Pliocene are, however, restricted marine deposits. It seems that towards the end of the Messinian the marine waters spilled over the western basins before they reached the east. The restricted marine facies of the uppermost Messinian in the Balearic and Tyrrhenian Basins are probably time equivalent in part to the upper *Lago Mare* deposits of the Ionian and Levantine Basins. The latter were inundated after the seawater spilled over Sicilian Channel. The early Pliocene (Trubi) inundation probably did not reach the Red Sea which was separated from the Mediterranean by the Isthmus of Suez. The marine invasion there was dated as occurring some 3.5–4 Myr ago, when a connection to the Indian Ocean was established through the Strait of Bab el Mandeb³⁵.

Pliocene flooding and Plio-Quaternary subsidence

Leg 42A drilling confirmed the Leg 13 drilling results that the first Pliocene sediments above the Messinian are deep and open marine hemipelagic sediments. The Messinian salinity crisis was ended by the Pliocene flooding.

Palaeobathymetric analyses indicated that the Pliocene sediments immediately above the Mio-Pliocene contact are in excess of 1,000 m, or 1,500 m in depth. The drilling evidence proved that deep Mediterranean depressions which had existed before the Messinian salinity crisis were still there at the end of the crisis. Seismic evidence indicates considerable Plio-Quaternary subsidence³⁶. The subsidence is in part induced by the isostatic load of the water flooding the basins⁴. Additional subsidence could be related to cooling of the mantle under the basins, or to continued tectonic activities which may have deepened the Mediterranean back-arc basins³⁶. There have been considerable Plio-Quaternary tectonic activities in the circum-Mediterranean regions. The evaporite basins of Sicily, Calabria,

Apennines, Tellian Atlas, Ionian Islands, Crete, Cyprus, and so on, were uplifted and emerged. Meanwhile continental margins locally (Nile and Rhone deltas, Israeli shelf, and so on) underwent subsidence³⁷. Those activities have modified the post-Messinian palaeogeography. The fact remains, however, that the Mediterranean basins owed their genesis to earlier movements, even though their floor may have been uplifted or subsided somewhat during the last five million years.

Impact of the Mediterranean salinity crisis

The desiccation of the Mediterranean took place 5.5 Myr ago. Such a geologically recent catastrophic event left behind not only a giant evaporite deposit, it also had a great impact on the modern world, on the circum-Mediterranean landscape, on regional and global climates, and on the evolution and distribution of plants and animals.

The lowering of the base-level of erosion led to the deep incision of rivers which drained into the Mediterranean⁴; even the southern Alpine lakes may have been Messinian canyons modified by Pleistocene glacial erosion³⁸. The exposure of Mediterranean bottom promoted an unusually active Late Miocene groundwater movement, which was probably responsible for the initiation of karst topography in Yugoslavia and in other Mediterranean countries. The uneven topography of the Mediterranean Ridge may have been a modified karst-development⁴, anomalous drilling behaviour noted during Leg 42A drilling on the Ridge suggests presence of submarine caverns.

The salinity crisis induced a continued change towards a cooler and more arid climate in the circum-Mediterranean. The Antarctic ice sheet expanded greatly during the Messinian³⁹, and the Arctic ice sheets may have begun to form then⁴⁰.

Biologists are only beginning to explore the implications of the Miocene Mediterranean desiccation. The present Mediterranean fauna is similar to that of the Pliocene, but very different from that of the Miocene, a fact noted by Lyell more than 100 yr ago when he first established the Miocene and Pliocene Epochs. The periodic conversion of an inland sea into dry land also permitted a migration of land animals; numerous examples of exchanges between Africa and Europe during the Messinian have been found^{41,42}. With the sudden Pliocene flooding, animals stranded on the Mediterranean islands would become isolated and develop endemism^{41,42}. Other usual aspects of the present Mediterranean land faunas may also be related to the unusual Messinian event. We might ask, for example, if the unusual habit of the circum-Mediterranean eels to breed in the Mediterranean, rather than in the Sargasso Sea, might be traced back to the time when the gate to the Atlantic was closed. We might also invoke the Messinian *Lago Mare* expansion to explain the similarity of relic freshwater faunas in France, Spain, and North Africa to those of the present Caspian. The impact of the Messinian salinity crisis and the accompanying climatic changes must have greatly influenced the distribution of land plants. The aridity led to temporary or permanent expansion of savanna vegetations. The impact on plant-evolution is subtle, but intriguing. It was suggested that some of the Mediterranean floras (for example *Medicago*) evolved from perennial to annual forms so as to endure longer period of severe drought, and from cross- into self-pollinators because insects could not have followed the new hardy plants into the hot dry environment (K. Lesins, personal communication).

We close this article in a contemplative mood. Biochemical studies suggest that the African ape-human divergence took place 5 or 6 Myr ago during the Messinian^{43,44}, just about the time when what is known to be the earliest hominid lived in Kenya⁴⁵. Is the timing

purely coincidental, or did the great expansion of the East Africa savannas at the time of the Mediterranean salinity crisis promote hominid evolution? Is our very being today traced back to that unusual event?

Catastrophic chemical events in the history of the ocean

William T. Holser

Max-Planck-Institut für Chemie, D-6500 Mainz, Germany (BRD)

Department of Geology, University of Oregon, Eugene, Oregon 97403

Catastrophic chemical events are characterised by sharp rises in $\delta^{34}\text{S}$ in the surface of the whole world ocean, and by greater overshoots locally. Three events are recognised and named for the formation in which they are most sharply displayed. The sharpness of the rise in $\delta^{34}\text{S}$ suggests that the sulphide deposition necessary to explain it must have been accumulating residual high- $\delta^{34}\text{S}$ seawater for some tens of millions of years out of contact with the surface ocean. A modified geological model is presented: brine generated by evaporite deposition is stored in deeps of a mediterranean basin; underneath the brine, pyrite precipitation builds a store of brine heavy in $\delta^{34}\text{S}_{\text{SO}_4}$, whose corresponding buildup of $\delta^{38}\text{O}_{\text{SO}_4}$ may balance the decrease of $\delta^{38}\text{O}_{\text{SO}_4}$ from evaporite deposition. Catastrophic mixing of the brine and the surface ocean, initiated by destruction of the storing basin, is the source of the sharp rise in the sulphur isotope age curve detected world-wide in evaporites. These events have important implications not only for modelling of the chemical history of the ocean, atmosphere, and sediments, but also for the explanation of faunal crises, and the many aspects of geology that depend on the composition and circulation of the oceans and their peripheral basins.

It has been known for some time that the sulphur isotope ratio in the world ocean surface has undergone major excursions during the period (Proterozoic-Phanerozoic) that could be documented from evaporite sulphate samples¹⁻³. The resulting sulphur isotope age curve has recently been updated with many new analyses of sulphur isotopes^{4,5}, supplemented by measurements of oxygen isotopes from some of the same sulphates^{5,6}.

The interpretations of these isotope age curves have focused mainly on explaining the trends of $\delta^{34}\text{S}$ as a result of widespread variations in biological reduction of sulphur into shales; on subsequent oxidative erosion into the sea; and with possible coupling of the carbon cycle to maintain atmospheric oxygen (refs 3, 5, 7-12). My purpose here is to discuss some more dramatic but less well-documented features of the isotope age curves, and to discuss whether they record catastrophic chemical events that are specific in time and place.

Upward jumps in $\delta^{34}\text{S}$

Fig. 1 shows as a solid line the mean best estimate for $\delta^{34}\text{S}$ in sulphate evaporite minerals in equilibrium with the surface of the world ocean^{4,5}. In constructing this curve greater weight was attributed to values whose world-wide distribution bore out their origin in the ocean surface as a whole, and less weight to results that were found in a narrow range of time and place. But it is worth noting that those of the latter deviations that are not so widespread may have considerable significance.

Marks on Fig. 1 highlight three rises in $\delta^{34}\text{S}$; and a solid line in Fig. 2 repeats these parts of the curve on an enlarged scale. These rises are so large and take place over such a short time, that I have labelled them chemical events by analogy with the nomenclature of magnetic reversals. Table 1 lists some characteristics of these three events. There are differences that may be significant, but some common features are: (1) The mean curve established by world-wide evaporite sampling rises sharply. (2) The rise is highly accentuated by a positive overshoot, in one formation in one basin, which gives its name to the event. The overshoot peak is a step function within the limits of stratigraphic control. (3) It is difficult to fix the absolute time interval within which the event is bracketed. Each seems to have taken place within one stratigraphic stage, probably much less than 5 Myr. (The times given in Table 1 are only scaled by inter-

Fig. 1 Summary sulphur isotope age curve for marine sulphate, from Claypool, *et al.*^{4,5}, who give detailed plots and lists of analyses. Data are shown here by areas or lines that indicate qualitatively the number of analyses, plotted at their most probable age. The heavy line is the best estimate for $\delta^{34}\text{S}$ in equilibrium with the world surface ocean of that time; the shaded area is an estimate of the uncertainty of that determination. The named catastrophic chemical events are sharp rises in the best-estimate curve, accompanied by very high values ('overshoots') found only locally.

polation from radioactive dates that are for the most part separated by a whole geological period¹³.) (4) Each of the events is followed by a long period of mean oceanic $\delta^{34}\text{S}$ that is higher than the pre-event level, and of course lower than the overshoot peak. This post-event level is either constant (YUdomski and Röt Events) or relatively slowly decreasing (Souris Event) over a substantial period of time. (5) The mean curve for $\delta^{18}\text{O}_{\text{SO}_4}$ in

marine sulphates⁵ at equivalent times displays either no discernible rise (YUdomski and Souris Events) or a relatively small one (Röt Event).

Nature of the chemical event

Models for interpretation of the sulphur isotope age curve explain general rises as indicative of marine biological precipitation of sulphide predominant over weathering of sulphide, and falls as oxidative sulphide weathering (refs 4, 5, 8, 11, 12), although the models differ widely in assumed constants, residence times, and couplings. Processes of a similar nature must also explain the sharp events.

Detailed consideration of the isotope geochemistry of oxygen has led Claypool *et al.*^{4,5} to conclude that when $\delta^{34}\text{S}$ rises a corresponding rise in $\delta^{18}\text{O}_{\text{SO}_4}$ can only be prevented if the sulphide deposition is accompanied by extensive evaporite deposition. This is possible because with oxygen, much more than with sulphur, the isotope effect of evaporite deposition tends to offset the effect of sulphide deposition. Consequently, the chemical events seem to have involved major and contemporaneous deposition of sulphide into anaerobic muds and of sulphate into evaporites.

But these rises in the sulphur curve, and especially the local overshoots, are so precipitous that an extremely high rate of sulphide precipitation would be required to change the whole world ocean so much in so short a time. One can first of all see qualitatively that if the residence time of sulphur in the ocean (with cyclic sea salt subtracted) is about 20 Myr, as at the present time³, then it will be very difficult to generate changes of 5–15‰ in $\delta^{34}\text{S}$ within 5 Myr, and still more so in 1 Myr. Nielsen² calculated that the rate of change of $\delta^{34}\text{S}$ probably would not exceed 0.3‰ per Myr. In making this calculation, he estimated the present rate of sulphur erosion ($\approx$ deposition) of 15 Mt yr⁻¹, but the maximum rate would have meant the complete suspension of erosion to get the calculated rate of rise from sulphur deposition. This seems unlikely, especially as present rates of erosion may be higher than usual¹⁴. Nielsen had also to use the current value of the sulphur content of the ocean. It is true, however, that if the ocean were smaller, the same rate of sulphide deposition would raise $\delta^{34}\text{S}$ correspondingly faster. Holland¹¹ also assumed the present sulphur content of the ocean, as well as the present rate of sulphur input by rivers (uncorrected for cyclic sea salt and anthropogenic sulphur). His values of rises in available oxygen for the intervals that span my chemical events can be converted to amounts (of sulphur deposited) that are correspondingly large,

Fig. 2 The chemical events labelled in Fig. 1 are shown here schematically on greatly enlarged scale. Solid line: best estimate for $\delta^{34}\text{S}$ of sulphate mineral in equilibrium with world surface ocean; shaded area: local high overshoot. The timing is based approximately on stratigraphic stages, so that the absolute time scale is very approximate.

Table 1 Catastrophic chemical events

Suggested name Stratigraphic stage	YUdomski Event Pre-Aldan (Latest Proterozoic)	Souris Event Frasnian (Lower Upper Devonian)	Röt Event Scythian (Upper Lower Triassic)
Approximate age (Myr) Pre-event level $\delta^{34}\text{S}$	575	355	215
Stratigraphic stage	Late Proterozoic	Eifelian (Lower Middle Devonian)	Mittlerer Buntsandstein (M. L. Triassic)
Approximate age (Myr)	635–850	365	220
Mean $\delta^{34}\text{S}$, ‰	+15	+18	+13
Earliest peak in $\delta^{34}\text{S}$ Formation	YUdomski Horizon	Souris River and others	Röt
Location	Eastern Siberian Platform	Saskatchewan	Netherlands to DDR
Other localities	Saline Series, Pakistan	—	Moenkopi of Utah
Maximum $\delta^{34}\text{S}$	Hormuz Series, Iran		
Maximum excursion in $\delta^{34}\text{S}$	+35 +20	+34 +16	+27 +14
Post-event level $\delta^{34}\text{S}$ Stratigraphic stage	Lower to Middle Cambrian	Famennian (Upper Upper Devonian)	Muschelkalk (Middle Triassic)
Mean level	+30	+23	+19
Rise of mean $\delta^{34}\text{S}$	+15	+5	+6
Rise of mean $\delta^{18}\text{O}$	0?	+0.5	+2.5

and when compressed into an actual rise time even as long as 5 Myr, the rate of net sulphur deposition figures out to about 150 Mt yr⁻¹. Using the simultaneous solution of mass balances for both sulphur and oxygen isotopes I have also calculated similarly extreme rates of sulphide deposition. These calculated rates all seem unlikely, and suggest that the deposition of sulphide that was responsible for the rise in the age curve was accumulated over a long period of time, but was read into the evaporite record in a very short time.

The first evidence of the event is also the strongest peak, and in at least the YUdomski and Souris Events is found in only one basin. This suggests a chemical overshoot, possibly in the very area where the event was generated. The post-event level is seen on the whole ocean's surface, and the eventual decline corresponds to a more uniform decay through the weathering process.

A geological model

To explain the 'Permo-Triassic faunal crisis' (which is coincident with my Röt Event) Fischer¹⁵ suggested that brine was generated on shelves from evaporite or near-evaporite conditions, and then slid down as a density current to accumulate in the ocean deeps. This mechanism generates a stratified ocean that is at least temporarily stable, with brine below and a brackish surface layer. The characteristics of the isotopic events suggest the following modifications of Fischer's proposal.

Fischer required brine that was to some undefined degree dense enough to stably resist mixing; he allowed but did not require that evaporation proceed as far as evaporite precipitation. The oxygen isotope data indicate that evaporites of at least the calcium sulphate facies were generated in large amounts. The resulting brine, of density 1.10–1.20 × 10³ kg m⁻³ has therefore all the more likely to be hydraulically stable in the bottom of a basin. Other proposals^{16,17} have been based on evaporite deposition in the halite facies, and that is not precluded here.

Fischer suggests a deep-sea depression as the storage site for brine. That is not necessary, and it may not be correct. The bottom of any basin will do for brine storage, so long as it is large enough to hold the amount of brine that must be sequestered to account for the change of $\delta^{34}\text{S}$. A rift graben or other mediterranean has the advantage that it is more susceptible to the quick destruction suggested by the fast rise of the $\delta^{34}\text{S}$ curve, which represents chemical mixing of the deep brine and the surface layer.

The suggestion of a large basin in which evaporite deposition (as well as sulphide deposition) is important will probably remind the reader of the desiccating sub-sea-level basin^{18,19}, which

enjoys inflow from the ocean without reflux. One problem with that arrangement is that in conditions approaching desiccation, the required mixing of the brine is inhibited. Valiashko²⁰ has pointed out that even at the beginning of the potash evaporite facies, the volume of remaining brine may be accommodated in the porosity of the previously deposited salts. But the basin could be sub-sea-level, and non-refluxing, so long as it was not desiccating.

It therefore seems most likely that the site for brine accumulation is neither a deep-sea basin, nor a sub-sea-level desiccating basin, but rather a large mediterranean isolated from the ocean, especially with regard to its deeps.

A particular requirement for the chemical event is that evaporite deposition be accompanied by sulphide deposition, within the same basin complex if not actually the same basin. Although many evaporite sequences are grey and evidently associated with reducing conditions, the amount of sulphide is usually small. So it may be that the major part of the sulphide deposition occurs under brine accumulated nearby. Some present saline deeps support bacterial reduction of the large proportion of sulphate that they still retain, while others are sterile. The differences are not understood^{21–23}.

Sulphide deposition requires not only the generation of sulphide by sulphur-reducing bacteria, but also a sufficient supply of iron (ferrous or ferric) to fix the sulphide in the sediment. Not much sulphide can be retained in solution in the brine, and even this would be ineffective for the chemical event if it were simply remixed with the ocean. Although sulphide deposition in ordinary bottom muds is usually supposed to get its iron from the sediments themselves (probably from hematite or goethite coating sand grains)²⁴, the amount required for building the large reservoir of fixed sulphide suggests that supplies could well be augmented from a more plentiful source such as submarine volcanism^{25,26}.

According to Fischer¹⁵ the fossil record suggests that during the Triassic the surface ocean returned to normal salinities. The sulphur isotope record also suggests this—but the sharp onset indicates a more catastrophic mixing of brine and surface ocean. At that time, in addition to the restoration of normal salinity described by Fischer, we may have a catastrophic inflow in various places of waters rich in salts, organic matter, sulphide ions, nutrients, oxygen demand, and $\delta^{34}\text{S}$. The local nature of the overshoot in $\delta^{34}\text{S}$ is further evidence for the catastrophic nature of the mixing. The location of such an overshoot suggests but does not necessarily prove that the brine was stored in a basin nearby.

In accordance with current custom much of the above can be stated in terms of the theory of plate tectonics. The rifting Atlantic is prominently associated with evaporites (refs 19, 27

Fig. 3 Geological model to explain the chemical events, somewhat modified from Fischer¹⁵. A basin or basin complex precipitates sulphate, and generates and stores brine, under which reduced sulphide is precipitated. The evaporites of the world (both left and right) sample only the surface ocean, out of contact with sulphate residues of the sulphide reduction, until its accumulated effect is catastrophically mixed with the surface waters at the time the basin complex is destroyed.

and 28); and Kinsman (refs 17, 29 and 30) has generalised and explained this association in the following way: rifting leads not only to initial rift valleys like the Red Sea, but also continuously generates subsiding continental margins, as well as transverse tensional grabens. These are all potential sites of restricted circulation and evaporite deposition along the trailing continental edge. Isolation may be aided by island-forming volcanism in the rift. Kinsman¹⁷ also pointed out the fast timescale of evaporite generation on specific sections of a continental margin—his time limit of 10 Myr is compatible with the chemical event reported here. I need only add to this description that brine sliding down and accumulating in the rift basin will help reduction of sulphide, and volcanic activity or associated thermal waters may supply iron and other heavy metals to fix the sulphide in giant deposits^{25, 26}. Eventual full separation of the continents mixes brine and surface ocean. This scenario is a possible one, but other tectonic situations may also generate the required structures and geography.

History of a chemical catastrophe

The story line is indicated in Fig. 4. At time *A* we find the sulphur isotope age curve slowly declining as a result of erosion of predominantly sulphide material into a mixed ocean. This erosion exceeds the sulphide deposition. At time *B*, dense residual brines from evaporite deposition begin to accumulate in the deep of a large nearby basin. Reduction to sulphide continues and $\delta^{34}\text{S}$ in the brine gradually begins to reverse and then increase, while at the same time its mass continues to grow as a larger and larger proportion of the ocean's sulphate is processed through the sulphate-sulphide production system. Meanwhile, the surface layer becomes more brackish, and its $\delta^{34}\text{S}$ continues to fall under the influence of the continuing erosion of older sedimentary sulphide. At point *C* the accumulated brine with high $\delta^{34}\text{S}$ begins to leak or mix slightly with the surface body of the ocean, slowing and even reversing the downward trend of $\delta^{34}\text{S}$ recorded in evaporites everywhere. At point *D* the climax of the event is reached as the brine is released, perhaps through tectonic destruction of the basin. Local appearance of the high $\delta^{34}\text{S}$ may be sampled by evaporites as an isolated record of $\delta^{34}\text{S}$ overshoot. Mixing of brine and surface water leads to an intermediate level of $\delta^{34}\text{S}$ in the subsequent evaporite sampling of the now mixed ocean. As erosion assumes greater importance again, at point *E*, $\delta^{34}\text{S}$ begins to decrease. This may continue until the required combination of evaporite production and basin geometry again induces brine accumulation.

Point *A* does not leave a record that I know how to recognise, so I don't know how long before the event brine segregation and accumulation began. It is conceivable that all the depressed sections of the $\delta^{34}\text{S}$ curve represent segregation and that therefore erosion never really takes over, but only becomes more evident when its depositional counterpart is hidden in a deep.

I realise that the explanation proposed for the chemical events is only a skeleton, and I exhibit it here so that others may join me in either giving it flesh or burying it. Whether it is viable or not the events are real and demand another explanation if not this one.

Geological model

Each of the events displays some individual character in the isotope age curves—these will now be described. And to follow up on the conjecture that the location of brine storage is flagged by the overshoot, the palaeogeography will be examined for conditions favourable to brine accumulation and sulphide reduction.

Yudomski Event. This event occurs just below the boundary of the Proterozoic and the Cambrian, between the Shaler Group of the Arctic Islands that can only be bracketed at 630–850 Myr (ref. 31), and the Yudomski Horizon of the Siberian Platform that is said to be dated at 600 ± 10 Myr (ref. 32). So the abruptness of the rise shown in Figs 1 and 2 is drawn by analogy to the later two events. Within the vague limits of the available data, $\delta^{18}\text{O}$ is unchanged throughout the whole event⁵. The level $\delta^{34}\text{S} \approx 17\text{‰}$ in the Proterozoic pre-event stage is puzzling. It could be an artefact of an imperfect record. Perhaps brine was accumulating all that time, leading to the climax of the chemical event at the Cambrian boundary. But in that case one would have expected the surface ocean as sampled by the evaporites to have shown a declining curve due to erosional input.

The earliest record of this event is an overshoot to 33‰ in our new analyses of the Yudomski or Motskaya Suite, which crops out around the southern edge of the Irkutsk Amphitheatre in Siberia. This horizon lies comfortably below the Cambrian³³, which especially in its middle stage developed into one of the world's largest evaporite basins²⁴. There are earlier evaporites, as yet unanalysed for isotopes, in Siberia that precede the Yudomski³². All of these Siberian basins opened in the direction of the present Arctic, and that could have been the locale for brine accumulation, but its palaeogeography and tectonics are unknown to me.

A possible alternative site for the main event is suggested by one analysis of high $\delta^{34}\text{S}$ in the Cambrian of the Salt Range of Pakistan⁶; this horizon evidently overlies the extensive Saline Series of possible Late Precambrian age³⁵, which may also be correlative with the very extensive Hormuz Series evaporites that extend across southern Iran^{36, 37}. This has been confirmed by unpublished high values of $\delta^{34}\text{S}$ obtained by Heimo Nielson (personal communication) from several samples of the Hormuz Series.

Souris Event. A special character of this event is a well-documented gradual rise in worldwide $\delta^{34}\text{S}$ during the Middle Devonian, that precedes the sharper rise to the peak in the Famennian Stage^{5, 7}. In terms of the model, this represents a more gradual leak or mixing from the stored brine into the ocean.

A strong overshoot is displayed in the Souris River Formation and related beds near the top of a giant sequence of evaporites that accumulated in the Elk Point Basin of Western Canada, beginning in the Middle Devonian. The basin was recharged from the north, across the strongly developed Presquile Reef in the North-west Territories. Beyond the reef black marine shales were extensively deposited³⁹, and this area may have been the place of brine accumulation and sulphide reduction. It lies at the edge of the Eurasian basin, whose palaeogeography and tectonics are still controversial^{39,40}.

Röt Event. This event occurs sometime between well-established low levels of $\delta^{34}\text{S} = 11\text{‰}$ in the latest Permian, and the moderate levels of the Middle Triassic and later Mesozoic stages. Although in many areas stratigraphic subdivision of the Lower Triassic has not been successful, analyses from the well divided Buntsandstein of East Germany⁴¹ and West Germany (unpublished data by Dietrich Rambow and Heimo Nielsen) show that low values of the Permian continue through the Lower and Middle part of the Lower Triassic.

The Buntsandstein exhibits a most dramatic overshoot, up to $\delta^{34}\text{S} = +27\text{‰}$, in the Röt (Upper Lower Triassic), whose evaporite facies extend from Poland across Germany (East and West) into England^{42,43} and touch Greenland⁴⁴. The main

Fig. 4 Schematic representation of sulphur isotope effects during the course of a chemical event. At the earliest time, *A*, $\delta^{34}\text{S}$ is slowly decreasing as erosion of sulphide exceeds deposition of sulphide. At *B* brine starts to accumulate in a basin complex as a result of evaporite deposition (Fig. 3), and biological reduction under the brine begins to slow and then reverses the decline of $\delta^{34}\text{S}$ in the residual sulphate in the brine, but out of contact with the surface ocean which continues to decline in $\delta^{34}\text{S}$ (as sampled by worldwide evaporites). At *C* the brine begins to mix somewhat with the surface ocean, and at *D* mixing becomes catastrophic, with local overshoot due to surfacing of deep brine. At *E* a level for the now mixed ocean is a weighted mean of the previous two reservoirs of sulphate; the course of this fictive mean isotope composition during the event is shown by the middle line.

development of Röt evaporites coincides with much of the thickest Zechstein evaporites. If, as seems plausible^{42,43}, the Röt and Zechstein had a common entrance to the north ('Skandik Sea'), this might furnish a suitable site for brine accumulation; although an alternative opinion is that the Röt was open to the Tethys Sea to the south-east⁴⁵.

A few analyses⁵ suggest a possible alternative site for this event, in the Lower Triassic areas of the Western United States.

Note that all three events have possible connections with brine accumulations in the region of the Palaeozoic geography that lies in the present Arctic.

Comparison with other theories

Thode and Monster¹ proposed that certain basins would have high values of $\delta^{34}\text{S}$, due to greater amounts of sulphur reduction, and they therefore assumed as a value for the world ocean the lowest $\delta^{34}\text{S}$ in any basin at a given time. In the present instance reduction in a basin is also proposed, on an even larger scale, but its residues remain out of contact with the world ocean surface until the catastrophic event of mixing.

Pilot *et al.*⁴¹ dealt specifically with the Röt event: They proposed that an accumulation of sulphide reduction in the Tethys Sea had been going on since the Carboniferous, and that the Röt evaporites were drawn from that sea, in contrast with the Zechstein which was drawn from the northern sea. For my model it is not sufficient to isolate Tethys and deposit sulphide there so that the Röt can tap it with a high $\delta^{34}\text{S}$ evaporite. The sulphide-depositing basin also has to derive a large amount of sulphate from the world ocean, while at the same time holding back its high $\delta^{34}\text{S}$ until a critical moment. I accomplish this with the evaporite-generated brine layer. This could have happened in Tethys, but for the reasons described above I think the northern sea is more likely.

Other speculations concerning the history of the ocean, while not specifically directed towards the interpretation of isotope age curves, are related to major chemical events. Buerlen¹⁶ proposed that the faunal crisis at the Permian-Triassic boundary might be connected with a decreasing salinity of seawater due to the extensive precipitation of evaporites during the Permian. As indicated above, Fischer¹⁵ had a similar explanation for this palaeontological problem, but made the surface ocean brackish by the accumulation of deep brines rather than necessarily by deposition of salt. His paper was the real ancestor of this one, but its significance was not appreciated until the isotope data had been accumulated in sufficient detail. Kinsman¹⁷ showed how the kind of events proposed by Buerlen (although he did not refer to either Fischer or Buerlen) may have been very strong during the early phases of a continental rifting. None of these proposals connected the generation of brackish surface waters with sulphide reduction, which is the main point of the new proposal. More recently, Degens and Stoffers⁴⁶ proposed that density stratification, of unspecified origin, may have been a common phenomenon in earlier seas, on the model of the present Black Sea. Reducing conditions in the brine and the sediment, and accumulation of organic material, are important aspects of the model of Degens and Stoffers. What I am adding to their model is an emphasis on sulphide deposition in the sub-brine sediment, a suddenness of re-mixing with the surface ocean, and a method of specifically detecting such situations in the geological record by the interpretation of the isotope age curves.

Catastrophic chemical events—implications for future work

(1) Modelling of ocean history and the calculations of oxygen demand (positive or negative) associated with sulphide-sulphate transfers will be more complicated than it has been^{4,11,12} under the assumption of a mixed ocean. In principle it will be possible to make new calculations with the sea sulphate divided between two reservoirs, surface and brine. Even without such calculations, one can say qualitatively that the overall decrease of $\delta^{34}\text{S}$ in the pre-event stage will be less

than that for the surface ocean alone, so that the maximum oxygen demand associated with a $\delta^{34}\text{S}$ minimum will be less than would have been calculated assuming a mixed ocean.

(2) The dominant sulphide reduction during the pre-event stage will be under the brine reservoir. Therefore during the deep minimum in the $\delta^{34}\text{S}$ evaporite curve, a corresponding $\delta^{34}\text{S}$ curve for these particular sulphides need not show such a deep minimum or, indeed, any minimum at all. Whether sulphides of the briny deep are mainly in black shales, as seems most likely, or also in large stratiform sulphide deposits, remains to be determined. The limited sulphur isotope data presently available for both styles of deposition have been reviewed by Schwarcz and Burnie⁴⁸, but these represent only a handful of occurrences.

(3) The combination of evaporite deposition and brine formation decreases surface salinity (in all its components) of the ocean during the pre-event phase. The surface ocean should also show a corresponding increase of δD and $\delta^{18}\text{O}_{\text{H}_2\text{O}}$, which should be looked for in fossils, limestones, and cherts, but on a finer time scale than previously tried^{15,48}.

(4) The decrease of sulphate in the surface ocean may allow the buildup, from erosional input, of elements such as barium and strontium; they may be precipitated during the subsequent mixing. Some sedimentary barite deposits^{49,50} coincide exactly with the Souris event; and peaks of strontium in shales are found near the YUdomski and Röt Events⁵¹. The age curve for $^{87}\text{Sr}/^{86}\text{Sr}$ shows a number of sharp rises⁵²⁻⁵⁴, and each of the chemical events postulated here has one of these jumps in $^{87}\text{Sr}/^{86}\text{Sr}$ associated with it: YUdomski Event—from 0.7075 in the Late Proterozoic (570 to 850 Myr?) to 0.7095 in the Lower Cambrian; Souris Event—from 0.7080 in the Givetian and Frasnian to 0.7093 in the Famennian; and the Röt Event—0.7073 in the Kazanian and Tartarian to 0.7083 in the Early Triassic. Veizer and Compston⁵³ noted that the fine structure of the strontium isotope curve might "... indicate that the fluctuations in Sr isotopic composition of seawater could develop within several million years." But the difficulty here is similar to sulphur—a residence time in a mixed ocean that is much longer than that.

(5) The possible effects of these various chemical changes on biological processes, ecology, and evolution may be far-reaching. Some of these have already been discussed in earlier models: pre-event increase in oxygen demand¹¹ (but less than previously assumed¹²), and decrease of surface salinity¹⁵⁻¹⁷. The new model would generate the added stress of a quick return to more or less normal salinity. The remixing of anoxic brines into the ocean may have profound effects, particularly in local regions of overshoot. Nutrients may be removed from effective participation in the biological cycle—temporarily with all seawater constituents, or by sedimentation under the brine. In the post-event stage re-mixing restores to the productive surface waters those nutrients still in solution, with consequent effects on organic productivity and possibly increased deposition of organic carbon and decrease of atmospheric $p\text{CO}_2$. A post-event increase in phosphate in surface waters may account for the proliferation of apatite-secreting metazoa in the Cambrian⁵⁵.

I thank my colleagues G. Claypool, I. Kaplan, H. Sakai, and I. Zak for many discussions in our quest to find the reasons for the isotope age curves. I am grateful for an appointment as Senior Scientist under the programme of the Alexander von Humboldt Stiftung, and for the hospitality of C. Junge and M. Schidlowski at the Max-Planck-Institut für Chemie, Mainz, Germany, where this paper was written. I thank H. Nielsen for stimulating discussion and access to unpublished data.

letters to nature

Future variation of Planck's constant

RECENT interest in cosmological models involving time-varying fundamental constants has stimulated experiments to measure such variations which may have occurred in the past. For example, the upper limit to past variations of h relative to other

fundamental constants has been measured as one part in 10^{12}yr^{-1} (refs 1 and 2). The purpose of this letter is to point out that the results of an experiment already performed by Partridge³ for a different reason, can be interpreted as setting a limit to the future variation of h over cosmological times.

In the quantum absorber theory of Hoyle and Narlikar^{4,5},

based on Feynman's path integral approach with a constant $\hbar$, it is the quantum mechanical response of the future part of the universe, rather than local field quantisation, which gives rise to spontaneous emission. This indicates the possibility of measuring future universal behaviour by experiments conducted in the present.

The method of modifying any form of quantum mechanics to allow for a hypothetical variation of $\hbar$ is of course not established experimentally. We can, nevertheless, proceed with reasonable postulates to generalise quantum absorber theory as follows. Consider a charged particle a at time t_0 , which is part of a quantum system such as an atom, in interaction with a similar particle b at some large distance away at a different time t_1 . If the interaction is negligible the quantum behaviour of a is determined by the dimensionless quantity $S_a/\hbar(t_0)$, where S_a is the free action for a and $\hbar(t_0)$ is the value of $\hbar$ at times near t_0 . (We assume the variation of $\hbar$ is small enough for $\hbar$ to be regarded as constant over short laboratory time scales.) A similar quantity $S_b/\hbar(t_1)$ determines the free behaviour of b . When the interaction is not negligible, an interaction term S_1 must be added to the action, and the question arises as to what value of $\hbar$ should be used with this term. In a completely time-symmetric universe some symmetric quantity such as $\frac{1}{2}(\hbar^{-1}(t_0) + \hbar^{-1}(t_1))S_1$ would seem appropriate, but in an asymmetric universe, in which only the future part provides a perfect absorber, it seems preferable to be guided by the self-consistent cycle of argument of Hoyle and Narlikar⁵ in which only retarded fields are used to calculate interactions. Thus if $t_1 < t_0$ the interaction is calculated from $-e\int_{t_0}^{\infty} \hbar^{-1} \mathbf{A}_b^{\text{ret}}(\mathbf{a}) \cdot \dot{\mathbf{a}} dt$ where $\mathbf{A}_b^{\text{ret}}(\mathbf{a})$ is the retarded field of b acting on a at position $\mathbf{a}$, and, since the integral is taken over an interval near t_0 , it is reasonable to take $\hbar = \hbar(t_0)$. On the other hand when $t_1 > t_0$, as it is when b is one of the particles of the absorber, the appropriate expression is $-e\int_{t_1}^{\infty} \hbar^{-1} \mathbf{A}_a^{\text{ret}}(\mathbf{b}) \cdot \dot{\mathbf{b}} dt$ with $\hbar = \hbar(t_1)$.

The values of $\hbar$ can be used to find the influence functional containing the quantum mechanical response of the Universe. The dependence of this functional on $\hbar(t_1)$, the value of $\hbar$ at the time of absorption, arises from the free action terms of the absorber and the interaction terms, and gives the way in which the lifetime of atom a in this modified theory depends upon the epoch at which absorption takes place. An experiment which can compare the transition rate in a source when the source is emitting into a local absorber, for which $\hbar$ takes its present value $\hbar(t_0)$, with the rate when the source is emitting into an absorber at a much greater distance where absorption takes place at time t_1 in the future, would thus give a measure of the future variation of $\hbar$ over the time scale $t_1 - t_0$. Just such an experiment has been done by Partridge³. In this experiment microwaves from a source were alternately directed into a local absorber and into the Universe. For the latter case Partridge estimated that at least 95% of the radiation would reach cosmological distances before absorption. The transition rate from excited states in the source was monitored by measuring the power needed to re-excite the source. Assuming a relation $P_1 = (1 - \delta)P_0$, where P_0 and P_1 represent the power used by the source in the presence and absence of the local absorber respectively, Partridge obtained a value $\delta = (1.1 \pm 1.6) \times 10^{-9}$. Although this experiment was performed for the different purpose of testing the completeness of the universal absorber, and the success in achieving this purpose has been questioned⁶, we can nevertheless use Partridge's data here. Writing $\hbar(t_1) = (1 - \Delta)\hbar(t_0)$ with Δ small, and using $\hbar = \hbar(t_1)$ in the influence functional determining the transition rate, we find that $0.95|\Delta| \approx |\delta|$. Taking the cosmological distances involved to be between 10^9 and 10^{10} light yr at least, gives an upper limit to the variation of $\hbar$ of about one part in 10^{18} yr⁻¹.

This result, which must be one of the longer time constants recorded, would be modified if, for example, the symmetric form of $\hbar$ mentioned earlier were used in the interaction term. The importance of the measurement however, lies not so much in the actual numerical result but in the fact that it is a measurement of the future variation of a physical quantity. It is important to

emphasize that this is not a prediction of future behaviour but, assuming the validity of the theory, is an actual measurement of behaviour which will occur. The apparatus 'sees' into the future.

Astrophysical X-ray spectra: alive and well

CRAIG and Brown¹ have repeated their doubts about the usefulness of high resolution X-ray spectra² and reiterated a series of inaccurate and misleading statements. For example, as early as their second sentence they incorrectly claim that "a high resolution spectrometer is almost invariably included in solar X-ray satellites". High spectral resolution can only be achieved with a collimated spectrometer, the total useful observing time of all such rocket borne devices being currently of the order of an hour. But no solar satellite has ever carried such a spectrometer and only one such device is planned to be in orbit before 1980.

Contrary to the impression given by Craig and Brown, high resolution solar X-ray spectra have found a wide application in the fields of solar physics, atomic physics and astrophysics. High resolution spectrometers are clearly required to resolve line blends, with spectral resolutions of $\lambda/\Delta\lambda \sim 10^3$ being required in some instances (ref. 3 contains several examples). When reliable line intensities have been obtained the atomic physicist has an abundant source of material. In the well known cases concerning Fe XVII (refs 4, 5) and the Helike ion satellite lines⁶⁻⁸, high resolution observations have stimulated formulation of more accurate theories, and progress on many other poorly understood ions is held up by lack of sufficient spectral resolution.

Abundances are fundamental astrophysical parameters that have also been derived from X-ray spectra, not by model-dependent methods as Craig and Brown mistakenly state, but by using line ratios which are insensitive to temperature⁹⁻¹¹. For future experiments further improvements in spectral resolution are planned so that true line profiles can be measured and line widths and shifts investigated.

The main problem worrying Craig and Brown concerns the expression for the intensity of a single spectral line in terms of a Fredholm integral of the type

$$p(a) = \int q(b) r(a,b) db$$

Such integrals occur frequently in astrophysics and the problems associated with solving such equations have been extensively discussed. Probably the most commonly encountered form of the above equation occurs in radiative transfer theory when expressing the emergent intensity of a stratified atmosphere in terms of the source function. The elementary approximation of a linear dependence of the source function on the optical depth has little physical significance. Neither does the Eddington-Barbier relationship which is subsequently derived, but the usefulness and accuracy of this end result cannot be disputed.

Given the inherent mathematical restrictions relating to the form of the above equation, progress on the astrophysical problem can only be made by adopting one of the following

procedures: (1) The use of a sophisticated matrix inversion technique, which helps to overcome the problems of 'bad' data and a limited range of observations, for example, Phillips-Twomey, Backus-Gilbert. (2) The derivation of a 'best fit' model with no *a priori* assumptions about its structure^{3,12,13}. (3) The derivation of a 'best fit' model with a predetermined analytical structure¹⁴⁻¹⁶.

At present solar X-ray observations are not of sufficient quality to justify the use of procedure (1). There is nothing inherently wrong with a 'best fit' model provided its limitations are recognised and it is used sensibly in its relevant domain. In fact most astrophysical models have been constructed using either (2) or (3) above: only the simplified situations seem to have exact solutions. Thus 'best fit' active region models are presently no less accurate than many other astrophysical models and they do have every prospect of improving when observations of more lines covering a wider temperature range become available.

Craig and Brown have used an elementary simulation to predict the intensities of several lines for an assumed structure. These line intensities are given a random perturbation and a model is computed. However, they overlook the fact that emission measures are everywhere defined as positive quantities. The problem of negative emission measures arises from using pairs of lines with broadly similar temperature responses such that small perturbations in the data lead to inverted flux ratios. Whilst it is true that none of the computed models seem to resemble the input structure, a simple averaging of these models, that is, a 'best fit' (or at least a 'better fit') gives a model closely resembling the input structure, indicating that a convergent (self-consistent) solution to the problem is possible.

In conclusion, it is safe to say that the interpretation of X-ray spectra is alive and well, and will continue to thrive with improved instrumentation.

'Best fit' models for solar active regions are just as accurate as any other astrophysical models and far from being 'spurious' are found to be in agreement with others derived from ultraviolet and optical data. X-ray astronomy in general, after several initial breakthroughs with 'quite simple detectors' will continue to make progress with telescopes having improved spatial resolution and spectrometers with improved spectral resolution.

those involved in space experiments, but their statements represent only one extreme viewpoint on this complex problem.

The main thrust of their argument is to point out the ill-conditioning of the equations that require to be inverted in order to carry out an analysis based on emission measures, and to illustrate this by reference to a 1970 publication by Batstone *et al.*³, an early attempt to do this in the X-ray region. It should be pointed out that emission measure analysis is only a small (though important) part of the full capability of spectroscopic diagnostics; that nowadays it is possible to combine it with spatial and time resolution of the source, and that the 1970 work is in any case not as unsound as they suggest.

To start with the last point, it is basic to all interpretational physics that the aim is to find the simplest model consistent with the observations. To insist, as do Craig and Brown, that all possible models, however complex, are equally valid and worthy of consideration would have seriously impeded progress in any branch of physics to which it had been applied. If we consider the histogram of emission measure X against temperature T from their example in terms of its Fourier components in harmonics of the temperature parameter, then it is clear that the simplest model is one with only low frequency components. The solution derived by Batstone *et al.*³ is a monotonic decrease from $T = 1$ to $T = 10$. Craig and Brown's alternative valid solutions all have for their largest amplitude Fourier component the highest harmonic permitted by the temperature interval— X oscillates violently up and down between each temperature point. Most physicists will recognise the unique nature of the simplest solution proposed by Batstone *et al.* in contrast to the contrived complexity of the alternatives. Furthermore, if we apply a simple smoothing (averaging pairs of adjacent points) all four models become very similar. Thus if we remove the highest Fourier component (normally spurious when fitting data based on discrete intervals) the physical reality of what is left is manifest by the fact that Craig and Brown's models, derived specifically to demonstrate the variability, tend to approach the same solution. The exception is the lowest temperature point, which remains variable to some extent due to the simple physical fact that the experiment is not very sensitive at these low temperatures. Craig and Brown, although right in demanding some form of error estimates in published data, are wrong in assuming that the full curve with all its temperature points is required in order to derive any significant conclusions from the data, and are also wrong in claiming that a single source temperature and variance could equally well describe the model. The significant data from this particular spectrum is probably describable by at most three points on an X against T curve, with the assumption of monotonic variation between them, and an asymptote at high T of zero. This is perhaps the limit of the information content, but such information can be very valuable. With modern space instrumentation techniques, data of this type can be obtained for a solar structure as a function both of position in two coordinates, and of time. Such a matrix of observations would provide a formidable challenge in the fitting together of theoretical and observational models. In practice, such a measurement nowadays would be likely to cover a much wider range of temperatures, and thereby further enhance its usefulness.

Emission measure analysis has long been used in the ultraviolet region for solar (and stellar) chromosphere structure determinations³. I have drawn attention⁴ to the limitations of this technique. In the ultraviolet case, however, the technique is much more precise than for X rays from active regions, and the limitations referred to above relate only to fine detail in the X against T curve. Craig and Brown claim that the method is always ill-conditioned due to the broad form of the kernel function F ; or to use the more usual Pottasch⁵ notation, the temperature dependent line factor $g(T)$. They claim that this is because F is always dominated by the Maxwellian electron distribution factor, $\exp(-E/kT)$. In this they are wrong. F contains the ion stage population N_i/N_e which is built up from

Why measure astrophysical X-ray spectra?

CRAIG and BROWN¹ advise caution against some of the limitations of X-ray astronomy, and emphasise the need to take theoretical considerations into account before planning expensive experiments. Their remarks must be taken seriously by

the product of many functions of the type $\exp(-E_i/kT)$ and consequently falls off much faster than a single function of this type, and in a way which varies with the wavelength region and type of ion chosen.

The above situation can be recognised more physically if we make an approximation to equation (1) of Craig and Brown

$$I(\epsilon) = \int_T \xi(T) F(\epsilon, T) dT \quad (1)$$

If the functions are transformed to a logarithmic temperature scale, so that $\theta = \log T$, then the kernel $F(\epsilon, \theta)$ can usually be approximated by a constant-shaped function, centred on a temperature θ_ϵ which is a function of the particular line ϵ . This is particularly true for the case dealt with by Batstone *et al.*², in which the lines are mostly isoelectronic, that is, they have similar atomic parameters, excitation energies and so on in relation to the charge on the ion. The equation can then be rewritten

$$I(\epsilon) = \int_\theta \xi(\theta) F(\theta - \theta_\epsilon) d\theta \quad (2)$$

Equation (2) can be recognised as a simple convolution integral in which the observable $I(\epsilon)$ is the result of folding the unknown $\xi(\theta)$ with a constant 'instrumental' profile $F(\theta)$. Its inversion properties are well-known; $\xi(\theta)$ can be derived from $I(\epsilon)$ reliably in regard to structure which is on a θ scale large compared with the width of $F(\theta)$, but becomes very ill-conditioned when trying to extract detail on a smaller scale than the width of $F(\theta)$. This simple approximation is useful to the physicist in understanding when the inversion of equation (1) is valid, and the inherent limitations in the solution obtained.

I now add a few remarks in defence of high wavelength resolution spectroscopy. The separation with confidence of spectral line blends into discrete lines opens up wide possibilities for the use of line ratios which, through the physics of the excitation mechanism, can be interpreted in terms of local electron temperature and density. This method can be much more precise than emission measure analysis, but is at present limited in its scope by limitations in the available atomic collision rates. The excitation process has a shorter relaxation time-constant in the plasma than emission measures which depend on ionisation balance. Consequently, the combined use of line ratios and emission measures can give vital information on the transient state of the plasma, that is the rate at which it is ionising or recombining. For solar X-ray measurements nowadays, lines and continuum can usually be separated. But, because of the lower fluxes, cosmic X-ray measurements so far have generally been broad-band, using the proportional counter as a spectrometer. Consequently, the expected strong line groups appear only as a bump in the spectrum, and it may be suspected that many of the 'continuum' measurements are contaminated by un-resolved lines. To suggest as do Craig and Brown that such crude detectors are more than adequate is therefore incorrect. When a future generation of cosmic X-ray spectrometers is able to resolve and separate lines, a whole new dimension of diagnostics will become possible and we can look forward to dramatic advances in our understanding of the recently discovered objects.

In conclusion, the field of spectroscopic diagnostics of space plasmas has come a very long way since 1970, when the emission measure analysis of a source, smeared over space and time, was a new development. We can now make detailed and precise measurements of a range of physical properties. Unfortunately, this calls for complex and sophisticated observational techniques, involving high spectral, space, and time resolutions and increased sensitivities. The criticisms levelled at emission measure analysis by Craig and Brown are not all sound, and ignore the proper role of such techniques within a broader

base which includes a range of more sophisticated techniques. Space experiments are not nowadays designed and built without input from theory. Most of the consortia currently in this field include members well versed in the present status of theoretical models, and with a broad understanding of the range of sophisticated diagnostic techniques currently available.

BROWN AND CRAIG REPLY—We do not refute the value of very high resolution spectrometry to atomic physics, nor in astrophysical abundance and line profile studies. However, grant proposals for satellite spectrometers of $\lambda/\Delta\lambda \approx 10^3$ usually identify $\xi(T)$ measurement as a primary aim (recognising that atomic line identification is harder to justify in an astronomy budget). Concerning the inference of $\xi(T)$ we reply:

Simplicity of models?—Gabriel's point of smoothness in $\xi(T)$ is well taken but a half sine wave in $(1-10) \times 10^6$ K fits the data and is simpler (one Fourier term less) than his "unique simplest solution" without remotely resembling it. It is also positive everywhere, which may please our critics, but so are about 500 other diverse meaningless solutions we generated¹ which fit the data. Strangely both authors claim convergence of our $\xi(T)$ from three random terms² when we proved¹ non-convergence after 10^4 terms! We agree with Parkinson that AR analyses may be "no less accurate than many other astrophysical models" and indeed recommend close scrutiny of the non-uniqueness of all such. Astrophysical plasmas are regrettably unaware that they should be smooth and simple^{4,5}.

Validity of analysis?—Gabriel's reference to convolutions and Parkinson's to radiative transfer integrals in fact amply vindicate our analysis. The extreme width of $F(\theta)$ in the former proves⁶ that $\xi(T)$ can only ever be crudely resolved so that high spectral resolution is futile for this purpose. Would Gabriel kindly reference one line whose temperature response width $\Delta T \ll \epsilon_{line}/k$? Parkinson correctly states that radiative transfer theorists regularly use linear source function approximations but they always emphasise that this crude result cannot be much improved by increasing data resolution (ref. 7 and J. T. Jefferies and Skumamich, personal communication) (for example more limb darkening coefficients)—precisely our point. We are well aware⁶ of the 'more refined' data reduction techniques possible but our critics seem unaware that these all heavily use *a priori* assumptions about the solution to augment the low information content of the experiment^{6,8}.

Originality and accuracy?—As far as we know we were first to: unambiguously define $\xi(T)$ physically; recognise the X-ray spectrum problem as a Fredholm equation and prove it ill-posed; use condition number analysis as a measure of maximum useful resolution in astrophysics. Fortunately others (for example ref. 7) do not share Parkinson's view that we have "added nothing new" and our analysis has indeed been used in Skylab data reduction⁸ and in Spacelab proposals. As to our alleged inaccuracy, Parkinson's opening example seems to be of semantic origin for in this context "high resolution" evidently means 10^4 – 10^5 whereas by his second paragraph "high resolution" has been reduced to $\sim 10^3$. Though for $\xi(T)$ analysis

even spectral resolutions greater than 10^4 – 10^5 are "high", spectrometers of $\lambda/\Delta\lambda < 10^5$ were in fact in orbit⁹ as early as 1967.

Night-time reception of solar radio events

RIIHMAA has reported night-time reception of a solar radio event¹. The observation, in the frequency range 20.85–23.20 MHz, was made at Kiiminki (65°05'N, 25°54'E) on 30 March 1976 with the Sun (and Jupiter) well below the horizon. Night-time reception of solar bursts had also been reported by Smith *et al.*². Such night-time solar radio burst reception might be brought about by anomalous propagation associated with plasma waves in the lower ionospheric E layer. I briefly discuss this phenomenon here and point out the possible importance of large ionospheric electric fields.

Riihmaa¹ argues that "in the present case the bursts must have been guided from the sunlit hemisphere over the polar regions. It may be significant that on the night of 30 March an auroral substorm and a strong blanketing sporadic-E (E_s) were observed. A suitable duct may have existed between the ground and the E_s layer." The total attenuation was estimated to be of the order of ≈ 10 dB (ref. 1 and personal communication).

The question arises as to what mechanism(s) may bring about the anomalous propagation of the bursts into the night-time hemisphere. Since ray bending and geometrical optics considerations do not seem to suffice, one may resort to a slightly more sophisticated approach.

An E layer in which electric fields above a nominal threshold of ~ 25 mV m⁻¹ excite Farley–Buneman waves^{3,4} of sufficiently large amplitude, may provide enough reflectivity to the ≈ 20 MHz radiation and 'guide' it over the polar region into the night-time hemisphere. I have considered the reflectivity of a Farley–Buneman unstable E layer in a brief paper on riometers⁵. For details see ref. 5 and refs therein.

In the present connection we need only note the following. Reflection of 20-MHz radiation (wavelength $\lambda = 15$ m) by a system of plane parallel plasma waves occurs by Bragg scattering when the relation $\lambda = 2\lambda_n \cos\theta$ is satisfied, λ_n being the relevant wavelength of the plasma waves and θ the angle of incidence. With $\alpha = \pi/2 - \theta \ll 1$ the above relation reads $\lambda \approx 2\lambda_n \sin\alpha \approx 2\lambda_n \alpha$. A typical angle α under which 20-MHz 'rays' from the Sun 'graze' from below the bottom part of the polar cap E layer and are reflected into the night-time hemisphere is $\alpha \approx 0.2$ rad $\sim 10^\circ$. Then the appropriate plasma wavelength for reflection is $\lambda_n \approx 40$ m. Plasma wavelengths of ~ 40 m (in the present case the geometry is such that λ_n is to be understood as the plasma wavelength along the geomagnetic field lines) are available among the Farley–Buneman waves generated by large electric fields in the E layer (ref. 5 and refs therein).

To compute the efficiency of reflection is a difficult task, but some estimates can be made. If we use equation (1) of ref. 5 for the (power) reflectivity R , a plasma frequency $f_p = \omega_p/2\pi \approx 4$ MHz, a percentage plasma density modulation $|\Delta n/n| \sim 0.1$, and a number of scatterers along the ray path $N \sim 10^4$ m per

40 m $\sim 2.5 \times 10^2$, we find $R \approx 6\%$, that is a reflectivity high enough for this reflection process to be of possible significance in 'guiding' the 20-MHz radiation into the high latitude night-side. Note that only one or at most two reflections from the ionosphere are required.

It seems of some relevance that, at the time of Riihmaa's observation, the K_p index was 4⁻, indicative of polar cap electric fields above the Farley–Buneman threshold. The possibility arises of testing the proposed mechanism by determining whether night-time reception of solar radio bursts occurs preferentially when large ionospheric electric fields exist over the polar cap. Were a correlation to be found, it would be in line with the observed correlation between high intensity polar cap electric fields and the occurrence of the Slant E Condition (SEC) in high latitude ionograms^{6,7}.

I thank Dr J. J. Riihmaa for helpful comments.

Why is the Maier–Saupe theory of nematic liquid crystals so successful?

THE Maier–Saupe theory of nematic liquid crystals is founded on a molecular field treatment of long-range contributions to the intermolecular potential and ignores the important short-range forces. Nonetheless this theory is particularly successful in predicting the orientational properties of real nematics. Here we propose a model which accounts both for the success of the Maier–Saupe theory and the failure of theories based exclusively on short-range forces.

The liquid crystal phase of a nematogen is characterised by the long-range orientational order which is destroyed at the transition to the isotropic fluid. The Maier–Saupe theory has been particularly successful in accounting, not only for the order–disorder transition, but also for the orientational properties of the nematic mesophase¹. The theory is founded on the molecular field approximation applied to a weak anisotropic pair potential; this then gives the effective orientational potential for a single particle as

$$U(\cos\theta) = \bar{u}_2 \bar{P}_2 P_2(\cos\theta)$$

where θ is the angle between the molecular symmetry axis and the director. The order parameter, $\bar{P}_2$, is the ensemble average of the second Legendre polynomial and $\bar{u}_2$ is a combination of the averaged anisotropic interaction parameters. Because the theory contains just one unknown, $\bar{u}_2$, the change at the transition in the order parameter ($\bar{P}_2^{(K)}$) and the entropy ($\Delta S^{(K)}$) are predicted to be universal properties of the nematogen. This prediction is in reasonable agreement with experiment; in addition the calculated values for $\bar{P}_2^{(K)}$ of 0.43 and $\Delta S^{(K)}/R$ of 0.417 are found to be in quite good accord with the observed values^{2,3}. The agreement with experiment can be made perfect by extending the Maier–Saupe theory in a variety of ways. These include the addition of terms to the intermolecular potential to allow for higher rank interactions⁴ and deviations from molecular cylindrical symmetry⁵ as well as by taking the molecular field approximation to higher order⁶.

We shall not consider these extensions, however, because our aim is to understand the reasons for the success of the Maier-Saupe theory rather than to improve it further. In particular we shall consider whether its achievements are accidental or whether they provide an insight into the role of short- and long-range forces in establishing nematic order. Despite its qualitative and even semi-quantitative success the Maier-Saupe theory has been widely criticised (refs 7, 8 and M. A. Cotter, in preparation). One of the major criticisms stems from the foundation of the theory on an anisotropic pair potential which is apparently determined solely by London dispersion forces⁷. As a consequence the nematic-isotropic transition temperature for an ensemble of rod-like particles is predicted to be^{1,4}

$$T_K = 4.541 \times 3h\nu\Delta\alpha^2/20k r^6$$

It is possible therefore to test the theory by attempting to calculate the transition temperature from a knowledge of the anisotropy, $\Delta\alpha$, in the molecular polarisability tensor. Thus order of magnitude estimates of $\Delta\alpha$ and the dispersive energy are found to yield transition temperatures which are considerably lower than those observed^{7,8}. Of course these estimates are themselves open to criticism because the internal electric field in an anisotropic medium is not well understood⁹. None-the-less it is doubtful if dispersion forces, as envisaged by Maier and Saupe, could be entirely responsible for the existence of liquid crystals.

A second attack on the theory is concerned with its complete neglect of anisotropic short-range repulsive forces which should be of special importance for the elongated molecules forming nematogens. This neglect would seem to be quite unjustified as it is now widely accepted that scalar repulsive forces have a dominant role in determining the organisation in simple fluids¹⁰. Such considerations have prompted the development of theories based on purely short-range anisotropic forces using a variety of approximations, which include the Onsager approach¹¹, lattice summations¹² and scaled particle theory¹³. In every case the order parameter and entropy change at the predicted phase transition were found to be much larger than their experimental counterparts. For example, the Onsager theory¹¹ gives the order parameter $\bar{P}_2^{(K)}$ at the transition as 0.85 which is over twice the value normally observed for nematics while the entropy change $\Delta S^{(K)}/R$ is predicted to be 8 which is in marked contrast to the observed values of about 0.3 (refs 2, 3). Of course the high length-to-breadth ratio of the constituent particles in the systems discussed by Onsager, are not realistic for a nematic, however the scaled particle theories do not suffer from this fault, and in addition, have been reasonably successful when applied to simple fluids¹⁰. None-the-less the predicted values of $\bar{P}_2^{(K)}$ are still found to be in excess of those determined by experiment, similarly the discontinuity in the density at the order-disorder transition is also predicted to be too large¹³. Such failings do not seem to be a consequence of the necessary approximations inherent in the theories for a computer-simulation experiment based on a continuous repulsive potential also yields an unrealistically high value for the order parameter¹⁴.

The theories based on interactions between hard particles suffer from another weakness, namely the absence of any direct dependence of the orientational properties on temperature. Thus, even though it may be reasonable to suppose that the order-disorder transition depends solely on density for a suspension of macromolecules, it is difficult to believe that density alone determines the transition in thermotropic liquid crystals. Indeed this failure is highlighted by the inability of these theories to account for the observed temperature dependence of the order parameter, $\bar{P}_2$, at constant volume¹⁵. In marked contrast the Maier-Saupe theory is able to provide a temperature dependence in very good agreement with experiment¹⁶.

We are faced, therefore, with an apparent dilemma. On the one hand theories based on short-range repulsive forces, which are expected to make the dominant contribution to the pair

potential, yield results in poor accord with experiment. While on the other hand, the Maier-Saupe theory, founded on long-range dispersion forces, provides an excellent description of the orientational properties of real nematogens. A formal solution to this dilemma is provided by the molecular field theories based on a completely general form of the total intermolecular potential⁴. This is separated into a scalar component and an anisotropic part¹⁷ which is then written in terms of the Pople expansion. The orientational part of the single particle potential is found to be a series whose first term has the same form as the Maier-Saupe result, although the coefficient $\bar{u}_2$ now contains, in principle, contributions from all anisotropic forces. The rapid convergence of the expansion for the single-particle potential is guaranteed, at least for nematics, by the marked decrease of the general order parameter, $\bar{P}_L$, with its rank L . Consequently, it is not necessary for the Pople expansion itself to converge rapidly; indeed, for small intermolecular separations the convergence is slow. The Maier-Saupe theory is, therefore, equivalent in form to one which includes both long- and short-range contributions to the anisotropic intermolecular potential.

There are, however, several unsatisfactory features of this analysis. In the first instance because all intermolecular forces contribute to $\bar{u}_2$ this is virtually impossible to determine and so the theory cannot be tested by calculating the nematic-isotropic transition temperature. By the same token, we are unable to discern which anisotropic forces are the most important for the formation of nematic liquid crystals. Finally, the general theory shows that the distance dependence of the anisotropic potential must be averaged over the pair distribution function appropriate for particles interacting with a purely scalar potential¹⁷. Such an averaging procedure seems physically unrealistic and so quite different schemes have been devised which allow for the anisotropy of the short-range forces.

Here we propose a solution to these difficulties. We suggest that both short- and long-range forces are important in determining the molecular organisation in a nematic phase but that they operate at quite different levels. In our model we suppose that the short-range forces are responsible for the formation of highly ordered groups or clusters of molecules. These forces may be repulsive as suggested by the behaviour of simple fluids, although with molecules as complex as those in nematogens specific anisotropic electronic interactions could also be involved. Physically we might imagine the cluster to be less anisometric than its constituent particles; as a consequence the anisotropic short-range forces between clusters would become of minor importance. Secondly, the anisotropy in the polarisability of the cluster will be approximately proportional to the number of particles in the cluster and so the dispersive interaction energy between clusters would become dominant. The net effect of the existence of clusters would be to reduce the anisotropy associated with the short-range forces while increasing the influence of long-range forces. The possibility of cluster formation was mentioned in the original Maier-Saupe theory¹ although its purpose seems to have been to force agreement between the predicted and observed entropy of transition. The other important ingredient of our model is the assumption that the clusters are not destroyed at the nematic-isotropic phase transition. The anisotropic forces between clusters are therefore responsible for the orientational properties of the nematic mesophase. The parameter $\bar{u}_2$ in the effective potential is not then determined by the interaction of two molecules, but by two clusters. Consequently, the coefficient $\bar{u}_2$ will be essentially proportional to the square of the number of particles in a cluster and so, even if dispersion forces did dominate the long-range interactions, it would still be possible to produce the necessary increase in the predicted transition temperature by the inclusion of a relatively small number of particles in a cluster. We can also understand the failure of theories based on repulsive forces. The fundamental unit in these calculations is a single particle and at the transition the orientational order is completely destroyed which produces a large increase in entropy. Whereas for the cluster model the transition unlocks the

ordering of the clusters but not that of the molecules within the cluster; consequently, the entropy of transition is small.

The notion of cluster formation in nematogens is apparently of value. It is important, however, to appreciate exactly what is meant by a cluster; indeed, such a concept has already been questioned because it was thought that the cluster should have some physical existence, as an independent object⁸. This existence is not necessary. In the language of statistical mechanics the cluster would be described in terms of the spatial and orientational pair distribution function. Then our model is equivalent to the assumption that the distribution function exhibits short-range order, over several molecular distances, and this order is not destroyed at the nematic-isotropic transition. Consequently, the variation in the orientational properties on passing from one phase to the other will be determined by the long-range intermolecular forces corresponding to distances over which the distribution function does change.

Finally, we must see if there is any other evidence, apart from the success of the Maier-Saupe theory and the failure of hard particle treatments, with which to support our model. Clearly, X-ray and neutron scattering studies are of particular significance because the scattering pattern is directly related to the distribution functions. Such experiments have been performed and they do support the cluster model. For example, the average intermolecular spacing is found from X-ray studies to be about 5.0 Å; this spacing exhibits a weak temperature dependence and is continuous at the nematic-isotropic transition¹⁸. In addition, the high local molecular order is also found to extend for about five molecular diameters but to be insensitive to temperature even at the transition. Preliminary investigations of 4,4'-dimethoxyazobenzene based on coherent neutron scattering also indicate the existence of high local ordering present in both nematic and isotropic phases but with the molecular planes stacked parallel¹⁹. There is additional, although less direct evidence for the existence and preservation of clusters above and below the phase transition. Thus the far-infrared or Poley absorption of 4-methoxybenzylidene-4'-*n*-butylaniline exhibits only a minor change in frequency as the temperature is varied through the order-disorder transition²⁰. Since the absorption frequency is determined by the short-range contributions to the intermolecular potential, these results imply that the short-range part of the distribution function does not change when the ordered phase is destroyed.

In conclusion, we assert that both short and long-range forces are important in determining the molecular organisation in a nematic liquid crystal. But, because the short-range part of the pair distribution function does not change appreciably at the nematic-isotropic transition, it is the long-range contribution to the pair potential which determines this transition. Consequently, the Maier-Saupe theory, founded on such forces, provides a good description of nematic liquid crystals, whereas theories based on short-range forces are invariably less successful.

New shock effects in the phosphide and carbide phases of Cañon Diablo iron meteorites

WE report a hitherto unrecorded variety of shock-induced damage in the cohenite, (FeNi)₃C, of a 'rim type' specimen of Cañon Diablo. The essential feature of the new effect is the wedge-shaped area of cloudy appearance that penetrates into the cohenite from the original cohenite-kamacite interface (see Fig. 1). The figure also shows the reheated, α_2 , condition of the kamacite and the dark-etching zone of carbon diffusion at the cohenite-kamacite interface; effects that have often been reported in 'rim type' samples of Cañon Diablo¹⁻³ and have been produced artificially by shock¹ or isothermal reheating⁴.

Fig. 1 Etched 1% Nital. Dark etching wedge of cloudy material penetrates structureless white cohenite. α_2 matrix, white, granular. Black carbon diffusion border at cohenite- α_2 interface. Note small unaltered phosphide on outer elbow of cohenite near centre of field. Field of view 0.63×0.42 mm.

Figure 2 represents the same feature at higher magnification and shows a characteristic pattern of swirls within the cloudy area.

Figure 3 is a scanning electron micrograph which demonstrates the duplex condition of the cloudy area. Microprobe point analyses of the light background in Fig. 3 were erratic but generally similar to unaltered cohenite, whereas point analyses of the dark inclusions consistently gave slightly higher nickel values. No phosphorus was detected within the cloudy area.

These observations were made on polished and etched sections of a 147-g specimen (number H 37.546 purchased from the American Meteorite Laboratory) and within this specimen numerous examples of the effect were encountered. Some of the cloudy areas in the cohenite were associated with incompletely reacted remnants of phosphide, which commonly occurs as small particles at the cohenite-kamacite interface. Larger areas of cloudy material extend deep into the cohenite crystals and sometimes completely transect them. In specimen H 37.546 these larger areas of cloudy material are occasionally accompanied by microscopically visible decomposition of the cohenite to graphite.

Under polarised light the cohenite appears polycrystalline but shows accentuated recrystallisation along the trace of

Fig. 2 Detail from Fig. 1 showing swirls within the cloudy wedge. Field of view 0.16×0.10 mm.

shear zones. Visible shear displacements were observed in the cohenite and in taenite. In the bulk kamacite any possible shear traces were obscured by the reheated, α_2 , condition but a small globule of kamacite that was enclosed by cohenite showed a sharply defined shear displacement that lay along a line of enhanced recrystallisation in the surrounding cohenite. Specimen H 37.546 also contained occasional filaments of phosphide located between adjacent kamacite bands. In most instances the only indication of shock reheating shown by this phosphide was the development of minor thorns⁴ at the phosphide-kamacite interface. However, a portion of this phosphide was found to show a fine duplex appearance similar to the cloudy areas observed in the cohenite. Microprobe analysis of this material showed no detectable change of nickel or phosphorus content when there was no detectable extension of the material beyond the original phosphide-kamacite interface. This effect may be called 'in-situ' melting of the phosphide; it appeared to be distributed along shear zones in the specimen and it has probably resulted from the effect of local shear superimposed on a general level of shock that was just insufficient to induce general melting of the phosphide.

The combination of shear, shock and reheating effects observed in this specimen are consistent with the following interpretation of the wedges of cloudy material observed in cohenite, Figs 1–3. The average or bulk level of shock in this specimen was not sufficient to induce melting of phosphide at the kamacite grain boundaries nor of the smaller phosphide particles at cohenite-kamacite interfaces. However, local shear, superimposed on the overall shock, provoked local 'in-situ' melting of phosphide. Some of the small phosphides at the cohenite-kamacite interfaces were

Fig. 3 Scanning electron micrograph of cloudy area in Fig. 2. Field of view 0.015×0.012 mm.

subject to this combination of effects and underwent incipient melting, with the result that the melt penetrated along shear zones in the carbide either as a wedge or as a more extensive band. In either case the process may be visualised as a combination of incipient melting, together with melt penetration along a zone of internal brecciation in the brittle cohenite. As judged by the extent of penetration this would result in considerable ($>10^{-3}$) dilution of the nickel and phosphorus content of the original phosphide. After these shock events the sample reverted to a residual temperature that was sufficiently high to allow some annealing of the earlier shock structure, as is shown by the visible graphitisation in the cohenite.

Following these observations on specimen H 37.546 we re-examined the 'rim' specimens of Axon and Couper² and found cloudy wedges as rare minor features in the cohenite of their specimens 34.5421; 34.2731 and 34.2737. However, the effect was pronounced in specimen 34.FRI. This latter specimen contained major shear displacements and also considerable quantities of shock melted sulphide which confused the identification of the wedge effect. Fortunately, sulphide is not present in the new specimen H 37.546.

A possible effect of ice ages on the Earth's magnetic field

ICE ages and reversals of the Earth's magnetic field are two widely different geophysical phenomena; but they may be casually linked by the following mechanism. The moment of inertia of the Earth will be changed by variations in size of polar ice sheets and the resulting redistribution of water mass. To conserve angular momentum the Earth's rotation must therefore change. Calculations on the basis of a simple model then suggest that conditions at the core-mantle boundary may be perturbed in such a way as to affect the generation of the Earth's magnetic field.

Although it is difficult to confirm a connection between climatic and geomagnetic changes, such a relationship could have important consequences in several fields. For example, the relatively well dated palaeomagnetic chronology could be used to increase the resolution of identifying and dating palaeoclimatic episodes; and modelling ways in which the reversal frequency of the Earth's magnetic field might change, or modelling even the mechanism of a field reversal itself, could be constrained by a need to be compatible with changes occurring from variations in the Earth's rotation. Also, this may be a mechanism for using solar energy to drive core motions.

A full analysis of the effect of variations in global ice volume and distribution on the Earth's speed of rotation would require a spherical harmonic approach. Although the formalism exists¹ the calculations do not yet appear in the literature. For simplicity, therefore, estimates of the order of magnitude of quantities involved are found from an idealised model to test if the hypothesis is worth further consideration. A rigid mantle is assumed to be decoupled from the core but initially rotating at the same rate. The atmosphere and ocean are assumed to

rotate with the mantle. The difference in inertia between a uniform layer of water, equivalent to a thin spherical shell, and a polar ice cap composed of the same mass of water circling the globe as an annulus is given by

$$\Delta I = I_s - I_i$$

where $I_s = (\frac{2}{3})Mr^2$ and $I_i = M(r \cos \phi)^2$, M is the mass of water or ice, r is the radius of the Earth and ϕ is the mean latitude of the ice sheet. Assuming that the angular momentum stays constant, then the change in rotational energy is given by $\frac{1}{2}\Delta I\omega^2$ where ω is the angular velocity of the Earth. Taking M as 4.3×10^{19} kg (equivalent to a sea level change of about 100 m), r as 6.4×10^6 m, ϕ as 60° and ω as 7.27×10^{-5} rad s⁻¹ then the change in rotational energy is 1.9×10^{24} J. The fractional change in the angular velocity, the length of the day and the moment of inertia is 10^{-5} , in agreement with other estimates². Because in the model the core is decoupled from the mantle there will be a relative velocity of around 2×10^{-3} m s⁻¹ at the core-mantle boundary. Complete coupling between core and mantle will change the core energy by about 1.9×10^{23} J, taking the moment of inertia of the core to be a tenth that of the mantle.

Before exploring the implication of these calculations, the effect of isostasy and changes in the Earth's gravitational potential will be discussed. The timescale for ice sheet growth or decay³ and the isostatic response time⁴ are often considered to be of the same order of magnitude, around 2,000 yr. Therefore if the growth or decay of an ice sheet is such that there is a linear change in the moment of inertia over a time T , and if isostatic adjustment occurs as an exponential change of the moment of inertia with a response time equal to T , then the maximum change in the moment of inertia is reduced by e^{-1} . The fractional changes in the length of the day and the speed of rotation of the Earth will be affected in a similar way. Although not contained in the model considered here, it is important to realise that even when an ice sheet has reached isostatic equilibrium there is still a small difference in the moment of inertia compared with the case where there is no ice sheet⁵; previous calculations of the effects of fluctuating ice volumes on the rotation of the Earth have usually assumed full isostatic compensation⁶ and have thus ignored the much larger transient changes. Farrell and Clark¹ have shown that the gravitational attraction of an ice sheet prevents eustatic sea level changes occurring as a uniform layer of water because the resulting ocean surface would not be an equipotential (that is, there is not a constant change in sea level worldwide). The effect is greatest near the ice sheet and only slightly increases the change in the moment of inertia previously calculated. Changes in gravitational and elastic energy are henceforth ignored.

Assuming a timescale of around 2,000 yr for variations in the size of ice sheets and for isostatic relaxation, an upper limit for the rate of average energy dissipation in the core would be 5×10^{12} W. Estimates⁶ of the power requirements for the geodynamo range from 10^9 to 10^{12} W. Therefore a perturbation of the magnetic field cannot be immediately discounted on energetic grounds. A possible core-mantle coupling mechanism for transferring energy to the core is one suggested by Hide⁷ to explain the decade variations in the length of the day, which are similar in magnitude to those arising here. Shallow topographic features at the core-mantle interface allow horizontal stresses to transfer angular momentum between core and mantle, whereas viscous and electromagnetic torques are not strong enough. Supposing that the polarity of the field depends on comparatively minor features of the pattern of core motions, Hide⁷ has suggested that changes in topography or the temperature field on the core-mantle boundary can lead to changes in the frequency of field reversals. The westward drift of the Earth's non-dipole field at around 3×10^{-4} m s⁻¹ has been thought to indicate the magnitude of core motions⁷. In the model considered here, this velocity would be reached after 300 yr. Timescales of this order seem to be present in some

features of the Earth's non-dipole magnetic field⁸. Precessional forces are an alternative coupling mechanism. They are thought to be insufficient to drive the geomagnetic dynamo⁹, but may still be large enough to modulate the magnetic field. Precessional torques at the core-mantle boundary would arise from changes in the mantle's principal moments of inertia⁹. Theoretical studies of dynamos generated by motions of a conducting fluid have shown their sensitivity to their boundary conditions⁹. It is therefore plausible that a continuous change in the speed of rotation of the Earth over a sufficiently long time could alter conditions at the core-mantle boundary and perturb the magnetic field or even cause a reversal. A number of mathematical models¹⁰⁻¹³ developed to explain the observed frequency distribution of polarity intervals all require reversals to occur by random variations in the orientation or distribution of subsidiary dipoles. It is therefore implied that the energy needed to trigger a field reversal could be much less than that needed to sustain dynamo action.

Evidence for a correlation between glacial periods and changes in the magnetic field is hard to evaluate because of the difficulty in accurately identifying and dating variations in both parameters. It is interesting though to speculate on a number of observed coincidences between changes in the magnetic field and in various other phenomena which might be explained by the hypothesis presented here. Wollin *et al.*¹⁴ have found from an examination of some deep-sea sedimentary cores that changes in intensity of the magnetic field could be correlated over the last 2 Myr with climatic changes represented both by variations in the population of foraminifera and by oxygen isotope changes thought to indicate fluctuations in ice volume. Kent and Opdyke¹⁵ have also found from spectral analysis of deep-sea sedimentary cores an apparent correlation between variations in intensity of the magnetic field and changes in the earth's obliquity. They suggest that the precessional force on the core will vary with the obliquity, and that their results reflect the modulation of a precessionally-driven dynamo by changes in the obliquity. Climatic changes affecting the precession of the earth could thus give rise to geomagnetic reversals. Hays¹⁶ has shown that past extinctions of faunal species have occurred nearly simultaneously with reversals of the magnetic field; climatic change associated with glacial activity could increase the environmental stress on the species leading to their destruction. Cox¹⁷ has shown that the reversal frequency of the magnetic field increased about 75 Myr ago and again between 50 and 35 Myr ago. The South Pole has been positioned over the Antarctic continent for about the last 80 Myr (ref. 18), Australasia parted from Antarctica about 50 Myr ago and the Drake Passage joining Antarctica to South America opened about 30 Myr ago¹⁹. This growing thermal isolation of Antarctica led to increasing glacial activity in the Southern Hemisphere²⁰. Harrison and Ramirez²¹ modelled the apparently limited extent of the Laschamp event by combining an axial geocentric dipole with another dipole near the core-mantle boundary beneath Europe; deglaciation of Northern Europe was contemporaneous with this magnetic event, and may be causally associated with it by affecting conditions at the core-mantle boundary. It may be significant that the time taken for the field to complete a reversal is of the order of a few thousand years, the same as the transient non-equilibrium behaviour of the earth at the beginning and end of ice ages.

I thank Professor J. A. Jacobs, Dr R. Hide and Dr D. Gubbins for their critical and helpful comments on some of the ideas expressed here.

The major stratospheric warming of 1976-77

MANY mid-winter warmings of the polar stratosphere have been observed in the last 25 years by means of radiosonde and rocket soundings and, recently, by satellites¹. Major warmings involve a reversal of the normal winter temperature gradient and zonal wind component in the stratosphere between middle and high latitudes. (In normal winter conditions temperatures decrease polewards and winds are westerly). We report here on the behaviour of the temperature and wind fields observed at various levels during a major warming and the indication that, in this case, similar changes occurred in both the troposphere and the stratosphere.

Fig. 1 Mean temperature ($\bar{T}$) over the cap north of 50°N plotted at two-day intervals. Climatological values of monthly mean temperatures, plotted at the mid-point of each month were derived from various publications: +, Crutcher⁴; ▲, Hanevskaja⁵; ■, Labitzke *et al.*⁶.

Fig. 2 1,000-500 mbar thickness anomalies (from the 1951-1970 average) for pentad 3, 1977 (11-15 January). Values are shown in geopotential decametres. ●, Grid points at which the anomaly is at least 4σ .

A stratospheric warming which began in December 1976 developed into a major event in January 1977, with zonal mean values of both temperature and geopotential height increasing polewards from 60°N at the 10 and 20 mbar levels. A full analysis of the energetics involved is not yet available (Labitzke *et al.*² have given a synoptic description of the event), but certain unusual aspects of atmospheric behaviour have become apparent from a study of objective analyses for the period.

The Meteorological Office produces twice-daily objective analyses of geopotential height fields at standard pressure levels for the Northern Hemisphere north of about 15°N and, from these analyses, fields of temperature and wind are inferred. We have processed the 00 GMT analyses on alternate days from late 1976, at seven levels (1,000, 500, 300, 100, 50, 20 and 10 mbar) to obtain, at each level, areal mean values of temperature and zonal wind component over the cap north of 50°N.

Variations of temperature during the present winter may be compared with climatological values (Fig. 1). Differences in the treatment of radiosonde data by individual organisations make it difficult to compare absolute values from different sources so the climatological values are included only to demonstrate the average shape of the temperature curves, with the tropospheric minimum occurring in late January or early February. The earlier climatological minimum at 10 mbar probably results from the occurrence, during the five-year period from which the stratospheric mean values were produced, of warmings which affected temperatures from late December onwards.

Two stratospheric warming periods are evident in Fig. 1, the first beginning in early November (during which derived temperatures were not available at 10 mbar) and the second beginning on 6 December and reaching a maximum around 3 January at 10 mbar. During the course of this second stratospheric disturbance, tropospheric temperatures also rose between mid-December and mid-January by some 2 to 3°C. The anomalies of 1,000-500 mbar thickness from the 1951-70 average for the pentad 11-15 January 1977 show (Fig. 2) predominantly positive values north of 50°N. This chart contains five grid points with anomalies of 4σ

Fig. 3 Mean zonal wind component ($\bar{u}$) over the cap north of 50°N plotted at two-day intervals, (westerly winds are positive). Allowance has been made for surface friction in calculating the winds at 1,000 mbar.

or more where σ denotes the standard deviation for that grid point derived from the 20 values for the corresponding pentad in the years 1951–70; they are all positive and are centred at 80°N , 90°W . The chart for the following 5-d period contains four grid points having similar anomalies; these are centred at 80°N , 145°E . Examination of corresponding thickness anomalies from 50°N to the pole for the previous six winters revealed that only at 21 grid points (of a possible 29,232) did the anomaly reach 4σ . The occurrence of nine extreme values in one 10-d period of mid-January 1977 is in marked contrast to this recent average of three or four per winter: this uncommon tropospheric warming during a stratospheric warming period represents a situation of obvious interest. On the other hand, the apparent lag between the start of the warming at the upper levels on 6 December and the warming in the lower troposphere (about 22 December) should not be interpreted as an indication that the tropospheric warming is caused by the stratospheric disturbance; the determination of any causal relationship between the warmings must await a full analysis of the energetics involved.

The mean zonal component north of 50°N ($\bar{u}$) 10 mbar reversed between 9 and 10 January (Fig. 3). This was associated with a reversal of the meridional gradient of zonal mean temperature in the stratosphere. However, the magnitude of the reversed temperature gradient and the corresponding rate of decrease of $\bar{u}$ with height were small at this stage (and indeed remained so in comparison with a previous major warming in 1967–68 (ref. 2)). The 10-mbar wind reversal was achieved largely because $\bar{u}$ in

the troposphere had also decreased; by 11 January easterlies were present at all levels.

The vertical continuity, so evident during the easterly period, was, in fact, present from late December onwards. A degree of continuity was also present during the minor warming in November minimum values of $\bar{u}$ (though still positive) occurred at all levels at approximately the same time (22–24 November). These results are consistent with the findings of Julian and Labitzke³ who provided evidence for an association between stratospheric warming and a reduction of the 500 mbar zonal wind component in the region 50°N – 70°N (used as an indicator of ‘blocking’). It may well be that the atmospheric behaviour observed during December and January represents an extreme example of this association.

The synoptic situation associated with the anomalously high polar temperatures and easterly winds of 15 January was dominated by a geopotential high near the North Pole at all levels from the surface up to at least 10 mbar. Tropospheric charts for the easterly period thus have much of the appearance of the typical stratospheric charts during warmings (though also containing features of higher wave numbers not present in the stratosphere). In view of this similarity between these two atmospheric layers it may be unjustifiably restrictive to describe the events as only a stratospheric warming.

Zonal winds associated with the dry period 1975–76 in England and Wales

THE low rainfall in England and Wales during the period May 1975 to August 1976 was discussed by Morris and Ratcliffe¹ and was shown to be associated with a progressive shift northwards in the position of the mean jetstream over the north-east Atlantic during the three successive years 1974–76. We report here that marked circulation changes in the 500-mbar (5.5 km) flow during the dry period occurred both in the vicinity of the British Isles and over the central Pacific. The flow is compared with an analysis of 5-d mean charts exhibiting blocking of the 500-mbar flow in the vicinity of the British Isles and it is suggested that the anomalous displacement of the jetstream during the dry period may have been associated with an eastward surge in the subtropical jet off south-east Asia.

The actual position of the maximum wind zones around the northern hemisphere varies from season to season but the mean position is conveniently shown by the mean geostrophic zonal west-east component at 500 mbar for the average period 1951–70 (Fig. 1). A northwards displacement of the jetstream occurs not infrequently when a blocking anticyclone is centred in the vicinity of the British Isles, with the shift usually lasting for 5–15 d. The mean zonal flow was studied on occasions when 5-d mean pressure anomaly

Fig. 1 Broken line, normal (1951-70) 500-mbar zonal components at 5 m s^{-1} intervals. Solid line, composite 500-mbar zonal components at 5 m s^{-1} intervals associated with a positive pressure anomaly in the vicinity of the British Isles.

charts showed a discrete positive pressure anomaly in the vicinity of the British Isles— $50\text{--}60^\circ\text{N}$, $0\text{--}20^\circ\text{W}$ (Fig. 1). On these occasions the maximum in the zonal flow is displaced to the north of the British Isles, further bifurcation of the flow occurs at 60°E , the maximum wind zone off south-east Asia extends further east than the normal position, and there is an eastwards displacement of the south-east Asian trough. Further analysis of the zonal flow shows an almost synchronous eastward surge in the

Pacific temperatures north of 40°N were colder than usual with a mean negative anomaly of approximately 1°C , while temperatures further south were close to normal. Miles³ has also shown that the Pacific was the only sector where the mean north to south temperature gradient in the atmosphere up to 500 mbar (5.5 km) was above average in the latitude band $35\text{--}55^\circ\text{N}$. Sea temperatures are normally conservative over periods of several months and in view of this it is thought that once an anomalous north to south gradient of

Fig. 2 Solid line, composite 500-mbar zonal components at 5 m s^{-1} intervals for between May 1975 and August 1976. Broken line, pseudo normal (16 months May to August 1951-70) 500-mbar zonal components at 5 m s^{-1} intervals.

500-mbar flow off south-east Asia throughout the year whenever a blocking anticyclone is observed near Britain.

This suggests that the displacement of the jet to the north of the British Isles during the dry period May 1975–August 1976 may have occurred in association with a similar eastwards surge in the subtropical jet off southeast Asia during the same period. Indeed an analysis of the zonal flow at 500 mbar during the dry period in England and Wales which lasted from May 1975 to August 1976 (Fig. 2) shows similar features including extension eastwards of the wind maximum off south-east Asia when compared with the average for the same period. The anomalies in the zonal flow are in the order of plus 4 m s^{-1} both to the north of the British Isles and between 180° and 160°W at 45°N , and are significantly different from the average at the 5% level, using Student's t test. The anomalous eastward displacement of the south-east Asian trough, also observed during the dry period, would by virtue of the hemispherical long wave interdependence result in downstream adjustments within a few days which on the timescales considered here would seem to be synchronous.

During the dry period 1975–76 it has been shown² that

temperature was established in the troposphere, the regime would tend to maintain the enhanced zonal flow over the Pacific and the anomalous eastward position of the south-east Asian trough. It seems, therefore, that the displacement of the jet to the north of the British Isles during the dry period from May 1975 to August 1976 occurred in association with an eastward surge in the sub-tropical jet off south-east Asia during the same period and that the anomalous sea temperature distribution over the Pacific was a factor in maintaining the enhanced flow.

Weak shock waves in the eruption column

RECENTLY Nairn¹ has made a study of the visible air shock waves which propagate above a volcanic vent in the form of luminous arcs and are closely followed by violent projections of gas and solid ejecta. In ref. 1 it is suggested that this event is caused by a strong explosion within the volcano due to a rapid heating of meteoritic water enclosed in lava pockets. Another type of shock wave formation accompanying volcanic eruption was recorded by one of us (L.D.L.) during an explosive phase of eruption in the Tolbatchik volcanic area (Kamchatka 1975). These waves were smoke and ash which could be observed as optically denser layers rising in the eruption column and probably cannot be attributed to burst phenomena. The present note is based on observations made near the end of the activity of cone II (the middle one in the photographs) when other newly-built pyroclastic cones already showed only weak fumarolic activity.

Over that time (27 August–9 September) the activity of cone II consisted of (1) ejection of a gas stream carrying a great amount of solid particles, (2) jets of ash, lapilli and blocks and (3) a liquid lava emission from the fissure near the cone's foot. Generally the three events took place simultaneously.

The lava temperature near the flow issue is estimated to be about 1,000 °C (ref. 2). The colour of the gas stream at the eruption column base and of blocks and fire jets, taking into account the screen formed by the smoke and ash through which they were observed, suggests they are at temperatures as high as 1,000–1,200 °C. However, the eruption column itself was not luminous and therefore the mean temperature of the gas probably did not exceed 600–400 °C.

Events (1) and (2) were practically continuous but occasional lulls of some 10 min or at most a few hours were recorded. Increases in the violence of gas emission so that even the side of the column exposed to the wind became quite upright—the so-called blastings—were noted also. As a rule the behaviour of the gas stream changed smoothly without any marked preliminary sign but it may be noted that sometimes before the end of a lull in (1) there was an intensification of (2).

In spite of such variations the explosive behaviour might be almost steady for many hours. At these times eruption was accompanied by a roar easily audible within a range of about 10 km and very similar to the noise of a reactive aeroengine fixed in one place. The eruption column was as high as 1 km or more.

At such periods of steady and fairly intense gas ejection one could observe thin optically denser layers cutting across the column. They travelled along the column from the rim of the cone to the cloud with a velocity—relative to the observer—greater than 1 km s⁻¹, most probably of the order of 1.5–3 km s⁻¹. When they met the cloud the layers expanded in diameter and broke up into several parts which in turn rapidly scattered on the lower face of clouds and it appeared to quiver as a result. The visible disintegration of the dense layers was followed by an acoustic shock from above producing in the observer the same sensation as do the air waves generated by aircraft passing through the sound barrier.

The phenomenon described did not occur often, but sometimes several layers followed one another at irregular intervals of some minutes or several tens of minutes.

Emergence of these travelling layers did not correlate with any appreciable changes in the regime of events (1) and/or (2) and was not preceded or followed by distinguishable underground bursts or shots. This behaviour contrasts with the strong atmospheric shock waves discussed in ref. 1: a weak shock wave travelling along the eruption column is unlikely to be connected with explosions within a volcano.

The nature of the explosions in cone II suggests an analogy with a nozzle through which the gas is discharged from the

Fig. 1 *a, b*, Layers of different densities. Photographs showing layers of different densities in the eruption column. Note that the high velocity of layer motion makes their images indistinct. (Photographs by L. D. Livshits).

Earth's interior to the atmosphere. The gas stream may be supersonic. If we assume that the rate of gas flow is sufficiently great that the flow is steady, we have a situation in which dense layers will form. For the estimation of flow rate the Bernoulli equation may be used

$$\frac{1}{2}v_0^2 + C_p T_0 = \frac{1}{2}v^2 + C_p T$$

Suppose that when the gas velocity v_0 is zero the gas temperature T_0 is equal to that of the surrounding rocks (= 1,000–1,200 °C) and that the specific heat $C_p = 1 \text{ J g}^{-1} \text{ K}^{-1}$. We

obtain the result that when cooling to 600–400 °C (the likely temperature of gas in the eruption column) the flow rate may be as great as 1,100 m s⁻¹. For a rough estimate of the sound velocity C in the gas at 600 °C the expression $C \approx (T/T_a)^{1/2}$ gives only about 600 m s⁻¹, where the subscript a refers to the atmospheric conditions. This indicates that the gas flow may indeed be supersonic.

The pressure on the nozzle exit is expressed by the equation

$$p = p_0 \left(1 - \frac{\gamma-1}{2} \frac{v^2}{C_0^2} \right) \frac{\gamma}{(\gamma-1)}$$

where p_0 , C_0 and p , C are the pressure and sound velocity of gas at the nozzle entrance and exit respectively.

If the jet pressure is a positive one ($p > p_a$) the jet stream will expand laterally (in the expansion wave). If the jet pressure is less than atmospheric ($p < p_a$), a pressure discontinuity of the shock type is initiated. In this shock wave (which is always a weak one) the value of the pressure is increased to p_a . To evaluate the gas outlet velocity v corresponding to $p = p_a$ we can use the expression

$$v^* = C_0 \left(\frac{2}{\gamma-1} \right)^{1/2} \left[1 - \left(\frac{p_a}{p_0} \right)^{(\gamma-1)/\gamma} \right]^{1/2} \approx C_0 \left(\frac{2}{\gamma-1} \right)^{1/2}$$

By putting $(p_a/p_0)^{(\gamma-1)/\gamma} \ll 1$, $C_0 \approx C_a(T_0/T)^{1/2}$, $\gamma = 1.4$ we obtain a value of v^* of approximately 1600 m s⁻¹. The value of v^* determines the position of the shock wave in reference to the nozzle exit: when the gas velocity v is greater than v^* the pressure in the channel is reduced and the shock wave moves upstream toward the nozzle entry; when v is less than v^* , the shock wave separates and moves in downstream direction. In 'normal' conditions such a surge would diverge and disintegrate right after separation. But the divergence of the weak shock wave under consideration here is oppressed by acting as a waveguide—the hot gas column is surrounded by cooler atmospheric walls of greater acoustic stiffness (the product of density and velocity of sound). So after separation the shock wave travels along the eruption column with a velocity equal to the velocity of sound in a hot gas. The velocity of the shock wave relative to the observer would be ~ 2 km s⁻¹ as was visually estimated.

In the cloud the acoustic stiffness of the column walls changes and the shock wave is able to diverge. The process is enhanced by reflections of the shock wave especially downwards against the supersonic gas flow. These create a zone of superpressure at the level of lower edge of cloud. The expansion of superpressured gas causes the visible effect of local motion in the lower part of the cloud and generates the sonic bang mentioned above.

The model presented here allows interpretation of phenomenon described in terms of the gas dynamics of the jetstream.

For strong shock waves the column of hot gas and tephra did not serve as a waveguide. Therefore the flashing arcs would pass in the atmosphere irrespective of presence of eruption column (as has been drawn by Perret³) or in its absence, as one can see on photographs in Nairn's paper¹.

Singlet oxygen in natural waters

MANY studies have shown that singlet molecular oxygen can oxidise a variety of organic substances^{1–7}. These studies have included biologically important compounds present in the aquatic environment such as amino acids^{4,7} and pollutants like polycyclic aromatic hydrocarbons⁵ and pesticides⁶. No data, however, have been obtained to demonstrate that reactions involving singlet oxygen (often called oxygenations) are sufficiently rapid to be significant in natural waters. The most likely mechanism for oxygenation in the environment was originally proposed by Kautsky⁸ by which light energy absorbed by a sensitizer is transferred to ground-state oxygen to form singlet oxygen, which in turn reacts with the organic substance, or 'acceptor' (A), to form a peroxide. Here we present evidence that rapid photochemical generation of singlet oxygen occurs in inland and coastal water bodies of the south-eastern United States.

Samples from selected water bodies were collected in pre-cleaned 1-l bottles with aluminium foil-lined caps. In all cases, water samples were obtained from the top half-metre of the water body and refrigerated at 5 °C before use. Very turbid samples from the Mississippi and a pond in Athens, Georgia, were centrifuged before use to facilitate analysis by liquid chromatography. All other samples were used with no pre-treatment. The samples exhibited a wide range of pH and total organic carbon. (Table 1).

The singlet oxygen, a short-lived species in water⁹, was chemically trapped by 2,5-dimethylfuran (DMF) that was added to the water samples. DMF was chosen because it is highly reactive towards singlet oxygen and its photo-oxygenation products have been well characterised¹⁰. Because DMF has a high tendency to volatilise from water, kinetic studies were conducted in cells equipped with gas-tight Teflon stopcocks. We analysed for DMF and the photoproducts by high-pressure liquid chromatography (HPLC) using 40% methanol–water as the mobile phase and ODS as the stationary phase.

Detailed product studies were conducted on the brown-coloured water from the Okefenokee Swamp. A solution of DMF in air-saturated swamp water was exposed to sunlight for an hour, then the products were collected on prewashed XAD-4 resin¹¹ and isolated by preparative HPLC. The major product (85% yield) was identified as *cis*-1,2-diacetylene by comparison of its mass and NMR spectra with spectra of an authentic sample (mass spectrum: m/e (rel. intensity), 112 (7), 96 (59), 69 (29), 43 (100); NMR (CDCl₃), δ 2.30 (singlet, 6H), δ 6.36 (singlet, 2H)). Two minor products were formed, one of which was identified as *trans*-1,2-diacetylene¹². Foote and his co-workers¹⁰ have shown that DMF reacts with singlet oxygen to form a peroxide which decomposes to diacetylene in water. HPLC analysis indicated that the same products were formed when solutions of DMF in the other water samples were exposed to sunlight. The DMF did not react in dark controls or when exposed to sunlight in distilled water.

To demonstrate further that singlet oxygen was an intermediate in these reactions, the effects of DABCO (1,4-diazabicyclo[2,2,2]octane) and deuterium oxide were studied (Fig. 1). The photo-oxygenations were strongly inhibited by DABCO, an efficient quencher of singlet oxygen¹³. On the other hand, and again consistent with the singlet oxygen mechanism, the reactions were more rapid in air-saturated 1:1 mixtures of deuterium oxide–natural water than in 1:1 mixtures of distilled water–natural water. The acceleration is attributed to an increase in the lifetime of singlet oxygen in the presence of deuterium oxide⁹. DABCO and deuterium oxide affected the reaction in Okefenokee Swamp water in nearly the same way as they affected photo-oxygenation of DMF using rose bengal, a known singlet oxygen sensitizer¹⁴ (Fig. 1).

When the concentration of acceptor is low, it has little in-

§Steady-state concentration of singlet oxygen.

fluence on the lifetime of singlet oxygen, τ , and the rate expression for disappearance of acceptor is

$$-\frac{d[A]}{dt} = \frac{I_a Y_s}{\beta} [A] \quad (1)$$

where I_a is the rate of light absorption and Y_s is the quantum efficiency for singlet oxygen generation¹⁵. The constant, β , equals $1/(k_A \tau)$ where k_A is the rate constant for reaction between

singlet oxygen and acceptor and τ is the lifetime of singlet oxygen^{1,9}. Data in Fig. 1 indicate that τ is about the same in distilled and swamp water. To determine values of Y_s for the water samples, air-saturated solutions of 10^{-4} M DMF in natural water and potassium ferrioxalate actinometers¹⁶ were exposed simultaneously to monochromatic light (366 nm) in a 'merry-go-round' apparatus¹⁷. Values of Y_s were computed from slopes of first-order plots, assuming that β for DMF is $1.2 \times 10^{-3} \text{ mol l}^{-1}$ in all the water samples⁹. These values ranged from a low of 0.014 to a high of 0.093 with an average of 0.043 ± 0.019 in our water samples (Table 1). In view of the reported complexity of the substances in natural waters¹⁸, the observed variation in quantum efficiencies was remarkably small.

Of particular environmental interest are the steady-state concentrations of singlet oxygen, $[O_2^*]$, that are photochemically generated by the action of sunlight. Near-surface concentrations of O_2^* were estimated by exposing 1-cm thick solutions of DMF (10^{-4} M) in the natural waters to sunlight in Athens, Georgia, (latitude 34°N) during December. Steady-state concentrations were assumed to equal $0.693 (k_A t_1)^{-1}$, where k_A is $4 \times 10^8 \text{ l mol}^{-1} \text{ s}^{-1}$, the rate constant for the reaction of DMF with singlet oxygen⁹, and t_1 is the first-order half life observed in the sunlight experiments (Table 1). Changes in $[O_2^*]$ were closely paralleled by changes in the rates of O_2^* generation at 366 nm, as reflected by the product, $F_{366} (Y_s)_{366}$ (Table 1). Taking the underwater solar irradiance values reported by Zepp and Cline¹⁹, we estimated that midsummer values are about three times higher than these midwinter values. The highest rates of singlet oxygen formation occurred in water from the highly coloured rivers of north Florida and the Okefenokee Swamp (first four in Table 1). These water bodies contain high concentrations of organics, most of which is fulvic acid, a complex humic substance derived from decayed plants¹⁹. Because most inland and coastal water bodies contain fulvic acid, it is reasonable to infer that photochemical generation of singlet oxygen is a widespread phenomenon in the aquatic environment.

The kinetic parameters in Table 1 can be used to estimate approximate half-lives for photo-oxygenation of dissolved organics in the aquatic environment. Using reported^{4,5} values of k_A , the following half-lives were estimated for photosensitized oxygenation of selected polycyclic aromatics and amino acids in the Okefenokee Swamp water: 7,12-dimethylbenz(a)anthracene, 6 h; naphthacene, 7 h; pentacene, 0.02 h; histidine, 2 h; tryptophan, 2 h; methionine, 3 h. The pesticide, *cis*-resmethrin²⁰, a furan derivative, must react at about the same

Fig. 1 Effect of DABCO and deuterium oxide on photo-oxygenation of 2,5-dimethylfuran (DMF) in Okefenokee Swamp water and in distilled water containing rose bengal; initial DMF concentration $[DMF]_0$, 1.0×10^{-4} M. Duration of light exposure expressed as fraction of half life compared with systems with no added DABCO or deuterium oxide (line *b*). *a*, 1:1 mixture of swamp water or 10^{-4} M aqueous rose bengal with deuterium oxide; *b*, 1:1 mixture of swamp water or 10^{-4} M aqueous rose bengal with distilled water; *c*, 1:1 mixture of swamp water of 10^{-4} M aqueous rose bengal with 0.019 M aqueous DABCO. rate as DMF. These half lives apply only to organics dissolved in the water. In water containing an appreciable amount of suspended sediments, extremely hydrophobic organics, such as polycyclic aromatics, exist in both the dissolved and sorbed state²¹. Nonetheless, the computed half lives do serve to indicate that singlet oxygen is likely to be an important intermediate in the transformation of certain pollutants and biologically important substances in lakes and rivers. Also, it is possible that the peroxides which form in singlet oxygen reactions may initiate the free radical oxidation of aquatic pollutants.

Finally, these findings suggest that singlet oxygen may be involved in the well known sunlight-induced fading of the colour in natural waters¹⁸. In preliminary studies of this phenomenon, we found that the Okefenokee Swamp water underwent considerable fading when exposed to sunlight for one full day. This fading did not occur when oxygen was removed from the water by degassing before sunlight exposure.

Low oxygen concentration extends the lifespan of cultured human diploid cells

THE pioneering studies of Hayflick¹ showed that normal human diploid cells of the WI-38 strain have a limited lifespan of approximately 50 ± 10 population doublings (PDL) *in vitro*. It is still not known to what extent this phenomenon is the result of the artificiality of the cell culture system: factors such as nutrition and ambient environmental factors may restrict the ability of these cells to express their true genetic potential. To what extent genetic and environmental factors act to constrain the lifespan of human diploid cells in culture is open to experiment. In the present study we have evaluated one important ambient factor of the environment, the oxygen concentration, on the growth and lifespan of two human diploid cell strains, WI-38 and IMR-90. Our results show that growth at oxygen concentrations less than 20% is enhanced and that an extension of about 25% of the lifespan of both cell types was realised by long term cultivation under 10% oxygen. This indicates that the potential for long term growth in culture of normal diploid cells may

Fig. 1 Effect of oxygen concentration on the growth of IMR-90 (a) and WI-38 (b) human diploid cells. Cells were grown in Eagle's Basal Medium with Hanks' salts (HBME, Pacific Biologicals) to which was added $50 \mu\text{g ml}^{-1}$ aureomycin (Lederle), $2.8 \times 10^{-2} \text{ M}$ N-2-hydroxyethylpiperazine-N'-2-ethanesulphonic acid (HEPES, Sigma) and 10% (v/v) non-inactivated foetal calf serum (GIBCO). Young WI-38 cells at PDL 23 and IMR-90 cells at PDL 19 were seeded in T-25 flasks at about 2,000 cells per flask and kept in a desiccator at 37°C at the indicated oxygen concentration for 10 d. Cell counts performed in triplicate for each oxygen concentration are given as relative values based on a value of 1 for the 20% oxygen cell counts: for IMR-90 this was 18×10^3 ; for WI-38 this was 28×10^3 .

be appreciably enhanced by more exact control of environmental factors.

We have studied the effect of oxygen concentration on growth and lifespan, primarily using WI-38 cells which are generally accepted to exhibit a limited *in vitro* lifespan¹. But the normal human lung strain IMR-90 has also received study more recently. Therefore, we felt it important to carry out parallel experiments using both types of cells. Cultures were tested periodically for mycoplasma by the culture method and found to be negative. Cell culture techniques have been described in detail elsewhere^{2,3}. WI-38 and IMR-90 cells were exposed to varying oxygen concentrations in the gas phase over the culture medium, and the effect on growth and lifespan evaluated. The term 'growth' as used in this study is meant as increase in cell number and not as increase in cell size. The population doubling level was used as a rough indication of culture age and is defined as a twofold increase in the number of cells seeded into a vessel².

Individual flasks were seeded with cells in culture medium. For growth studies, cells were seeded at 0.25×10^6 cells per flask and triplicate flasks were counted daily from days 2-7 inclusive of incubation at various oxygen concentrations. For plating experiments, cells were seeded at a low density (2,000 cells per flask) and cells and colonies were counted after 10 d of growth (with no media change) under varying oxygen levels. The flasks were then flushed for 1 min at a flow rate of 1.5 l min^{-1} with various proportions of oxygen in nitrogen with carbon dioxide held constant at 5% at 1 atm and 20°C . The following combinations of gas were used: 2% O₂, 93% N₂, 5% CO₂; 5% O₂, 90% N₂, 5% CO₂; 10% O₂, 85% N₂, 5% CO₂; 20% O₂ (added as 95% dry air which contains 19.99% O₂), 5% CO₂; and 50% O₂, 45% N₂ and 5% CO₂. The gassed flasks were placed in

250-mm desiccators from which the air was removed by vacuum and replaced with the gas mixture used in flushing the flasks.

In short term growth studies, within a given series of subcultures, we have generally observed that concentrations of oxygen below 20%, particularly between 5 and 10%, speed up the growth rate. When the results of many experiments are averaged, however, the results were usually found not to be statistically valid. If cells are seeded at lower density, however, the effects of lowered oxygen concentration on cell growth are apparent, relative to cells grown at 20% oxygen; cells cultivated at 10 and 2% oxygen show much increased growth rates (Fig. 1). Such results are similar to the increased clonal growth rates of cultured cells of various types reported previously^{4,5}, that less than 20% oxygen concentration enhances the growth rate of mammalian cells cultured either attached to the substratum or in a suspension culture (compare with ref. 5).

Although neither WI-38 nor IMR-90 showed reproducibly greater rates of short term growth, it seemed possible that cumulative effects of lower oxygen concentration might be seen in lifespan studies, particularly since cell growth was always inhibited, even in the short term, at oxygen concentrations greater than 20%.

A typical series of experiments showing the effects of 10, 20 and 50% oxygen on the lifespan of WI-38 cells is shown in Fig. 2. At 50% oxygen, the cells phase out after two subcultivations, whereas the control cultures grown at ambient 20% oxygen exhibit a finite lifespan of 56 population doublings. When grown continuously at 10% oxygen, the cells did not phase out until 68 population doublings had elapsed. Table 1 summarises four series of experiments with

Fig. 2 Effect of oxygen concentration on the lifespan of WI-38 human diploid cells. The parent flask at PDL 18 was subcultivated at about 2.5×10^6 cells per flask in duplicate for each oxygen concentration. Every 7 d the cells were trypsinised, counted, subdivided and regassed. A solution of 0.25% trypsin in Ca- and Mg-free balanced salt solution (Pacific Biologicals) was used to detach cells from flasks for subcultivation. Cell counts were determined using a haemocytometer, or by Coulter Counter Model P64. When necessary, the pH of the culture medium was adjusted by adding 7.5% sodium bicarbonate. PDL was determined by the split ratio used in the subcultivation and is derived from the equation $n = n_0 2^x$ where n = final cell number in a single culture, n_0 = starting cell number, and x = number of doublings². Once each week, cultures were split at ratios of 1:4 for 2×10^6 or more cells, or 1:2 for 1×10^6 to 2×10^6 cells, and the PDL was estimated by adding 2 population doublings at each 1:4 split or 1 PDL at each 1:2 split. If the number of cells was less than 1×10^6 they were resuspended and reseeded. If cells had not reached confluence, they were fed. When cultures would no longer grow into a confluent monolayer of cells within 3 weeks after a 1:2 split following addition of fresh medium each week, the cultures were considered to be at the end of their lifespan. Δ , 10% O_2 ; $\bullet$, 20% O_2 ; $\circ$, 50% O_2 .

WI-38 and two series with IMR-90 with 10% oxygen, showing that cell lifespan is enhanced on average by about 25%. In one case, series 46B for WI-38 where the oxygen concentration was lowered to 10% only after PDL 52.5, the benefit in lifespan extension was only 9%. This suggests that extension of lifespan by lower oxygen may be realised at any stage in the lifespan, and the effect of oxygen concentration on long term growth may be cumulative.

In other studies not reported here (J. Walton collaboration), we have found that cells maintained under 50% oxygen show extensive morphological damage, particularly to mitochondrial and membranous structures. No apparent morphological changes were observed between ambient oxygen and 10% oxygen, except that the morphological changes usually associated with phase III (the senescence phase), were delayed in cells grown at lower oxygen.

The ambient oxygen concentration of 20% normally used in cell cultures is probably higher than that to which cells are exposed *in vivo*. Although cells have evolved several mechanisms for counteracting oxygen toxicity (namely superoxide dismutase, glutathione peroxidase), the possibility remains that cumulative damage arising from O_2 and products of oxidative metabolism may limit the lifespan of cells both *in vivo* and *in vitro*. Previous studies^{4,5} have demonstrated that the growth of cells after low cell density seeding can be enhanced by lowering the oxygen concentration below ambient; in static culture, clonal growth of WI-38 and adult monkey cells was observed by Taylor *et al.*⁴ to be enhanced by lowering the oxygen in the gas phase from ambient to 1%, and that variable growth and reduced plating efficiencies occurred in cultures grown at ambient 20% oxygen. Similar findings were reported by Richter *et al.*⁵ both for neoplastic and non-neoplastic cells from foetal tissues. Our results are consistent with these findings. Furthermore, we have now evaluated the long term influence of lower oxygen concentration on growth of normal human diploid cells in static cultures, and show that an average extension of the lifespan of 25% can be achieved by lowering the oxygen concentration from 20% to 10%.

Oxygen is essential, yet it may be inhibitory for growth if its steady-state concentration is below or above optimal. For two normal human diploid cell strains, 10% O_2 seems to provide optimum conditions for long term growth in culture. In a similar study, Balin *et al.*⁶ reported no extension of WI-38 lifespan by O_2 concentrations between 5.6 and 50 mmHg; the effect of 75 mmHg, equivalent to 10% O_2 , was not investigated; furthermore there was no stimulatory effect with low O_2 , and the same inhibitory effect with high O_2 as we have observed⁷ was found. This suggests that further studies on the effects of oxygen and oxidative damage on cells in culture are important. Other factors which have been reported to extend lifespan of normal human diploid cells (compare refs 3,6-8) such as

hydrocortisone, serum, additional bovine serum albumin and vitamin E, should be evaluated alone and in combination, under lower oxygen concentrations. The extent to which cells can be cultivated *in vitro* in more optimal environmental conditions can thus be determined. The wide use of normal human diploid cells as model systems for ageing studies and virus production, for example, indicates that immense benefits could result if such cells could be cultured on a long term or indefinite basis *in vitro*.

We thank Ms Joyce Kirkham for assistance with preliminary experiments and Dr Judie M. Walton for discussion and collaboration on the cytotoxic effects of O_2 . We thank Dr Hayflick (Stanford) for starter cultures of WI-38 and the IMR-90 starter cultures were from the Institute for Medical Research, New Jersey. This research was supported by the Energy Research and Development Administration.

Mutation and inactivation of mammalian cells by various ionising radiations

THERE is almost no information on the mutagenic effectiveness of the various ionising radiations for man and only limited information about radiations other than X or γ rays for experimental mammals. We have measured inactivation and mutation induction in cultured mammalian cells exposed to various radiations covering a range of linear energy transfer (LET; ref. 1). We show for two cell types that the maximum mutagenic effectiveness of these radiations, relative to X or γ rays, is about twice that for inactivation. Preliminary experiments suggest that specific chromosome aberrations may be associated with mutations induced by radiations of high LET.

LET is a measure of the deposition of energy along the tracks of the charged particles produced in irradiated material. The distribution of energy loss events along a track depends on the type of radiation; events are widely-spaced for radiations of low LET such as X or γ rays, but more closely spaced for radiations of higher LET such as α particles (as from plutonium) and the protons and other secondary ions produced by neutrons in tissue. The effectiveness of a radiation in producing a particular biological response relative to that of X or γ rays is known as its relative biological effectiveness (RBE; see ref. 2 and Table 1 legend). The yield of mutations per unit absorbed dose of radiation in lower organisms and plants is affected by LET (ref. 2). High dose-rate (acute) irradiations of mice have shown that the RBE of fission neutrons for the production of several types of mutation is about 6 in spermatogonia and about 4.5 in maturing oocytes³. RBEs of about 20 for mutation induction have been found after low dose-rate (chronic) irradiation of spermatogonia by fission neutrons³. But neutron irradiations produce tracks of widely differing LETs (for fission neutrons the range is about 10 to over

500 keV μm^{-1}) and the observed RBEs give little indication of the variation of RBE with LET. Compared with whole mammals, cultured mammalian cells offer the advantages of rapidity of assay and ease of irradiation, especially when the radiation is poorly penetrating, and also the opportunity for more detailed analysis of the mechanisms of mutagenesis. Quantitative estimates of mutation induction by low LET radiation can be made for cultured mammalian cells⁴, including freshly-isolated human cells, using a mutation system based on loss of the activity of the purine salvage enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT).

Cultures of freshly-isolated human cells and established V79 hamster cells were irradiated with helium, boron or nitrogen ions covering an LET range of 20-470 keV μm^{-1} . Table 1 gives the coefficients of the dose-response curves for inactivation and mutation by these radiations (see Table 1 legend and ref. 5). The RBE_a is the ratio of the linear terms (α coefficients) of the respective dose-response curves. For hamster cells, however, the RBE varies with dose because the shapes of the dose-response curves change with LET (ref. 5). This is seen in Table 1 which gives values of RBE at low doses (RBE_a) and an example of values at higher doses (RBE_{HD}).

A plot of RBE against LET for the human cells is shown in Fig. 1 and for the hamster cells in Fig. 2. The variation of RBE with LET for inactivation and mutation induction in both cell types shows similar humped forms with maxima in the LET range 85-200 keV μm^{-1} . In this LET range the RBE for mutation induction was about twice that for inactivation. In hamster cells, this approximately twofold difference in RBE values was not influenced by the response level at which RBE was determined (Table 1).

The forms of RBE-LET relationships in Figs 1 and 2 can be explained if mutation or cellular inactivation require that one charged particle should leave either (1) several energy loss events in a single sensitive cellular component or target⁶⁻⁸ or (2) one energy loss event in each of two targets⁹⁻¹². On hypothesis (2) the two targets could be the two strands of a DNA duplex (diameter ~ 2 nm)¹⁰⁻¹².

If the dimensions of the target are small, then differences in the track structure of different ions of similar mean LET,

Fig. 1 RBE-LET relationships for freshly-isolated human diploid fibroblasts. Open symbols, mutation induction; closed symbols, inactivation. $\diamond$, $\blacklozenge$, 250-kVp X rays; $\circ$, $\bullet$, ^4He ions; $\triangle$, $\blacktriangle$, ^{10}B ions; $\square$, $\blacksquare$, ^{14}N ions. Data points are RBE_a values of Table 1. An arbitrary LET value has been assigned to X rays within the range given in ref. 1.

such as track width and LET spectrum, may influence the relative effectiveness of the radiation. Some of our data are consistent with this idea, as seen in the difference between the RBE for boron ions of $110 \text{ keV } \mu\text{m}^{-1}$ (track width $\sim 1,000 \text{ nm}$) and for helium ions of $90 \text{ keV } \mu\text{m}^{-1}$ (track width $\sim 40 \text{ nm}$) for the inactivation of hamster cells (Fig. 2). But, since these differences were not found for the human cells other mechanisms may be involved; for example, differences in the abilities of the two cell types to repair radiation damage^{13,14}.

There is some evidence from the work of others that the

different types of mutation induced by ionising radiation may have different RBE-LET responses. With high LET helium and carbon ions the maximum RBE for deletion mutations in *Neurospora* was greater than that for point mutations⁷. Similarly, in the *d-se* region of the mouse genome, more than twice as many multifunctional mutations were produced by fission neutrons than by X or γ rays¹⁵. These multifunctional mutations are believed to arise mainly as a result of deficiencies (deletions)¹⁵, suggesting a higher neutron RBE for deficiencies than for mutations at single loci.

Cultures of freshly-isolated human fibroblasts (HF19) and an established line of Chinese hamster cells (V79-4) were maintained in Eagles minimal essential medium plus 10% foetal calf serum (Gibco-Biocult) using methods previously described^{20,21}. In most experiments cells were spread on to dishes with thin plastic bases (ICI Melinex), incubated overnight, and then irradiated without medium present. Techniques used for the various radiations are described in ref 5. Track intersection irradiations with ^4He , ^{10}B and ^{14}N ions were carried out at the variable energy cyclotron and the van der Graaf tandem accelerator of the AERE, Harwell. Methods of irradiation and dosimetry were similar to those of Neary²² except that the dishes were held in a wheel which rotated continuously during the irradiation to bring each dish in line with the beam a number of times. The average absorbed dose rate during each irradiation was $40\text{--}120 \text{ rad min}^{-1}$ which correspond to instantaneous absorbed dose rates of $2\text{--}9 \text{ krad min}^{-1}$ during the time that each dish was in the beam. The LET values are based on stopping power data for water assuming a density of 1 g cm^{-3} .

The survival of irradiated cells was usually estimated by their ability to grow and form colonies on the Melinex dishes after incubation periods of 7 d (hamster cells) or 12 d (human cells). Some survival estimations and all mutation estimations were made with cells respread after irradiation on to polystyrene dishes or bulk culture vessels²³ with normal growth medium. Mutants deficient in HGPRT activity were selected by resistance to the cytotoxic purine analogue 6-thioguanine⁴. To detect the maximum number of these mutants amongst irradiated cells, the cells were allowed different periods of post-irradiation growth in normal medium and then were respread into medium containing 6-thioguanine. Factors affecting the detection of radiation-induced mutants of this type have been described in detail elsewhere^{13,14,21,24}. For human cells the logarithm of surviving fraction and the induced mutation frequency per viable cell were both linearly related to dose, while for hamster cells these quantities were most simply described by a quadratic equation. Consequently the data points, weighted by the inverse of their variances, were fitted by the method of least squares to the following equations:

$$\begin{aligned} \text{hamster cell surviving fraction, } S/S_0 &= \exp -(\alpha D + \beta D^2) \\ \text{human cell surviving fraction, } S/S_0 &= \exp -(\alpha D) \\ \text{hamster cell induced mutation frequency, } M &= \alpha D + \beta D^2 \\ \text{human cell induced mutation frequency, } M &= \alpha D \end{aligned}$$

where D is the dose. The best fits for the coefficients α and β are listed above; the errors shown are simple standard errors (s.e.) of each coefficient in turn with the other at its best fit value. RBE values are derived either as the ratio of α for any given radiation to α for X or γ rays (RBE_a) or, for the hamster cells only, also as the ratio of doses required to produce 10% survival or an induced mutation frequency of 6.8×10^{-5} (this frequency is found after a dose of γ rays yielding 10% survival) (RBE_{HD}). The results given for helium ions of 20 and 28 $\text{keV } \mu\text{m}^{-1}$ and for nitrogen ions of 470 $\text{keV } \mu\text{m}^{-1}$ are from single experiments; two or more experiments were carried out for the remaining LETs.

Fig. 2 RBE-LET relationships for established V79 Chinese hamster cells. Symbols as for Fig. 1 except $\diamond$, $\blacklozenge$, ^{60}Co γ rays. Data points are RBE_{HD} values of Table 1. An arbitrary LET value, comparable to that given for X rays in Fig. 1, has been assigned to γ rays within the range given in ref. 1.

No current genetic techniques for somatic cells can distinguish small deletions from point mutations. In man, however, the HGPRT gene is known to be located on the long arm of the X chromosome¹⁶ and gross genetic changes associated with loss of HGPRT may be detectable in mutants of cultured cells by chromosome banding techniques. Our preliminary results with ASG banding¹⁷ show that visible aberrations in the long arm of the X chromosome occur in about 40% of HGPRT-deficient mutants induced by nitrogen ions of high LET. In contrast, X-chromosome aberrations have not yet been detected in spontaneous and X-ray induced thioguanine-resistant mutants.

These preliminary observations suggest that an additional mutagenic mechanism becomes important with high LET irradiations. We previously found a simple relationship between inactivation and mutation induction by low LET radiation in cultured mammalian cells^{4,18}, and an additional mutagenic mechanism operating at higher LETs could explain the higher maximum RBE for mutation induction relative to inactivation (Figs 1 and 2). It is not yet possible to distinguish between two alternative molecular processes which might be involved in this additional mechanism: (1) that a different type of mutagenic lesion is induced by high LET radiation or (2) that lesions similar to those induced by low LET radiation are modified or interact after high LET radiation to give an increased probability of the lesions becoming mutagenic.

The implications for radiobiological theory of the data summarised here will be discussed more fully in subsequent publications. It is clear, however, that these data provide useful empirical confirmation of current radiological protection standards. The recommendations of the International Commission on Radiological Protection on maximum permissible doses for radiation effects in man include 'quality factors' (Qs) which are intended to allow for the effects of LET. The maximum Q is given as 20 (ref. 19), in agreement with the RBE for mutation induction by chronic irradiation in the mouse, and this is sup-

ported by the RBE_s obtained here for mutation of cultured hamster cells by low doses. The cultured human cells showed a maximum RBE for mutation induction somewhat less than this maximum Q. We should stress that the RBE values found for mutation to HGPRT-deficiency in cultured cells are probably averages of the RBEs for more than one type of genetic change, as discussed above. Consequently other mutations, perhaps comprising different combinations of genetic changes, might have RBEs different from those found here.

We thank our colleagues for experimental assistance and for comments on the manuscript, and the staffs of the AERE accelerators, Harwell, for their cooperation.

Note added in proof: We now have evidence that X-chromosome aberrations are associated with thioguanine resistance in a proportion of mutants induced by both low and high LET radiations, but that different types of aberration predominate at different LETs.

Group and mass effects in diprionid sawflies

THE larvae of gregarious insect species, when reared as single individuals, have a significantly higher death rate than do solitary forms¹. This has been demonstrated in diprionid sawflies, where all main genera have solitary and very gregarious species². It has been argued that this high mortality is due to starvation, because only one in three of the newly hatched larvae of the gregarious *Neodiprion pratti* could feed successfully on the tough pine needles, whereas larvae in a colony could join and enlarge feeding sites, thus benefiting from an elementary 'division of labour'³. Our experiments, however, have not confirmed such a mechanistic explanation.

Improved rearing techniques kept larval mortality at ~10% for most species, including the solitary *Diprion frutetorum* and the scarcely gregarious *N. abietis*. A consistently high mortality was encountered only in individually reared first instars of *N. lecontei*, which is undoubtedly the most gregarious species we have studied. The most unexpected results were the very low mortality of isolated first instars of the two gregarious species *N. rugifrons* and *N. pratti* (Fig. 1). Although most deaths in these experiments occurred in the first instar, they were not, as has been claimed, caused by starvation. More than 70% of the larvae had fed before they succumbed. Paradoxically, it

was the doomed isolated first instars of gregarious forms that produced many more feeding incisions than did the larvae that were reared in groups (Fig. 2). Psychological factors entered into the situation to change the behaviour of the larvae. These were indicated by an increased restlessness of the larvae which wandered for long periods between each feeding bout and sometimes left the foliage altogether. This disjointed behaviour could be stabilised by the addition of more larvae to the experimental situation, until a species-specific group size was attained when feeding became normal and mortality was low. This threshold was reached with five larvae in *N. lecontei* on red pine, but with a smaller group size on jack pine, the optimal host available to this group (Fig. 1).

Colonial feeding in social animals is often associated with better weight gain and thus shorter rates of development. No such effect was noticed in *N. lecontei* when isolated and group-reared animals were compared. Singly reared *N. pratti* larvae took 30% more time to complete their feeding stages than their brother and sister reared in aggregations. The ecological implications of a mechanism that reduced the exposure time to enemies are obvious, although by no means the only benefits accruing from a gregarious habit. The larvae discourage their attackers by the discharge of a viscous, repellent liquid and the synchronous beating of head and thorax. These activities not only result in reduced losses but also in a disproportionately high survival of individuals in the centre of the colony, at the expense of those located at the periphery⁴.

The intensity of aggregative behaviour in diprionid larvae is eclipsed by other sawflies, many of them confined to the Southern Hemisphere. Females of the Brazilian *Themos olfersii* (Argidae)⁵ and the Australian *Pseudoperge guerini*⁶ guard not only their eggs but also their young larvae for several weeks. Cooperation in the *Pseudoperge* larvae is especially important just after hatching when they have to fight their way through the tough epidermis of the *Eucalyptus* leaves in which the egg pods are placed. Similarly, mature larvae have to penetrate the hard crust of the soil to spin their massed cocoons underground. Larger groups clearly succeed much better at both tasks. Cohesiveness and conspecific attraction of *Pseudoperge*

Fig. 1 Larval mortality of *Neodiprion* spp. in six experimental situations. A group effect was observed in *N. lecontei*, where an increase in the feeding aggregations resulted in a linear decrease in mortality up to a species-specific group size (which was five larvae on red pine, the natural host, but only four on jack pine). *N. abietis* showed a mass effect, whereas mortality in *N. pratti* was unrelated to group size. ●, *Neodiprion lecontei* on red pine (*Pinus resinosa*); ○, *N. lecontei* on jack pine (*P. banksiana*); ▲, *N. pratti* on jack pine; ■, *N. abietis* on balsam fir (*Abies balsamea*).

Fig. 2 Feeding patterns of *Neodiprion* larvae 1–6 d old. The mean numbers of feeding sites per larva were significantly different for each species ($P < 0.001$). Large feeding aggregations resulted in normal feeding patterns. In small groups the gregarious *N. lecontei* showed disjointed behaviour resulting in scattered feeding sites (compare the two drawings) accompanied by high mortality (Fig. 1). The difference in number of feeding sites is significant ($P < 0.001$) between groups of three and four larvae for *N. lecontei*, whereas for *N. abietis*, the scarcely gregarious species, such a difference exists only between one larva and a group of two. These differences correspond to species-specific group sizes. No such effects were observed for *N. pratti*, thereby explaining its low mortality. ●, *N. lecontei*; ▲, *N. pratti*; ■, *N. abietis*.

larvae is unrivalled by Northern Hemisphere sawflies. Fifty larvae of all ages spaced regularly on a paper grid 50 cm × 50 cm coalesced within 25 min to form an intertwining mass inseparable without the use of anaesthesia. Gregarious *Neodiprion* larvae by contrast, showed only feeble interest in one another when similarly tested. The presence of food caused the formation of large, stable groups but even dry, inedible foliage encouraged temporary groups of two or three larvae to be formed.

Although gregarious behaviour, or its absence, has led to obvious morphological and behavioural modifications, it seems that the greatest impact for most species concerns their ecology and population dynamics. The tenthredinid sawfly genus *Pikonema* illustrates this hypothesis well. Two related species feed on spruce, but whereas *P. alaskensis* is common and kills trees, *P. dimmockii* is never abundant or a threat to its host and the reason for this is found in the behavioural patterns of the larvae. The gregarious *P. alaskensis*, unlike the solitary *P. dimmockii*, does not get alarmed by frequent contacts with other larvae but resumes feeding soon after contact. *P. dimmockii* larvae wander for long periods after each encounter and settle down only with difficulty⁷. This suggests that two opposite types of density-dependent adaptations have evolved in larval sawflies. The reciprocal sensory stimulation in the larvae of gregarious species causes a group effect⁸ that enhances the optimal development. A similar stimulation creates a mass effect⁹ with often lethal consequences in solitary species. Similar subtle pressures seem to have operated in the rearing experiments with *N. abietis* (and *D. frutetorum*), where a clear relationship was established between increasing population density and higher larval mortality (Fig. 1). The primitive sociality of some gregarious species is of special interest since interactions between group mates of a feeding aggregation may eventually explain the emergence of cooperation in the complex societies of wasps, bees and ants.

Oestradiol and its biosynthesis in *Phaseolus vulgaris* L.

UNTIL recently the presence of steroidal oestrogens in plants has been a matter for debate¹, and any physiological significance associated with them has been generally disregarded^{2,3}. Although steroidal oestrogens have been found in extracts of a few species⁴, the identification of oestrone in *Phaseolus* was based on equivocal procedures⁵. Moreover, as with any compound present in low concentration, it is possible that at least some of the oestrogens identified in plant extracts are attributable to external contamination. This risk can be eliminated by demonstrating the incorporation of radioactive label from a known precursor into the compounds of interest. We report here the incorporation of radioactive isotopes from (3RS)-2-¹⁴C-mevalonic acid DBED (MVA), 4-¹⁴C-oestrone and potassium 6,7-³H-oestrone sulphate into oestradiol by *Phaseolus vulgaris* L., cultivar Canadian Wonder. This represents the first case known to us of successful labelling of an identified steroidal oestrogen from ¹⁴C-MVA in a higher plant. It seems therefore that this class of mammalian sex hormone is produced in plants as well as animals.

Eight-day-old seedlings of *P. vulgaris* were sectioned under water at the base of the hypocotyl, stood in aqueous solutions of the various radioactive substances and allowed to transpire for 5 d (ref. 6). They were then planted in potting compost and grown for 2–5 weeks to facilitate normal growth and development. Harvested plants were solvent extracted (chloroform:methanol:2:1) under reflux in a Soxhlet apparatus for 8 h. The extract was reduced to dryness *in vacuo* and taken up in ether. The phenolic fraction was isolated by partitioning with 1N NaOH, followed by acidification of the aqueous phase and repartitioning into ether. Thin-layer chromatography (TLC) and column chromatography on Sephadex LH-20 were used to isolate those fractions expected to contain oestrone (E₁) and oestradiol (E₂).

The chromatographic mobilities of metabolites were compared with authentic compounds using TLC on three solvent systems (chloroform:methanol:95:5; benzene:propan-2-ol:95:5; petroleum ether:ethyl acetate:75:25), column chromatography on LH-20 of the underivatized extracts and radio-gas-liquid chromatography (radio GLC) on OV-101 of the trimethylsilyl ether derivatives. Samples believed to contain oestradiol were diluted with non-radioactive carrier oestradiol and recrystallised to constant specific activity.

Using these techniques in combination, ¹⁴C was observed to be incorporated into oestradiol from MVA and from 4-¹⁴C-oestrone. Similarly, oestradiol could be labelled from the

³H-oestrone sulphate. Attempts to label oestrone have not been conclusive; the rate of incorporation from radio-active MVA into the putative oestrone peak was much less than that observed for oestradiol.

One previous report describes the incorporation of ¹⁴C-MVA into a phenolic fraction by the higher plant *Haplopappus heterophyllus*, but the radioactive phenolic material did not correspond to any common steroidal oestrogen⁷. There have been many studies of the biotransformation of the mammalian steroid hormones progesterone and testosterone^{4,8}, but our findings seem to represent the first report of a metabolic transformation of an oestrogen in plants—reduction of the 17-keto steroid E₁ to the 17β-hydroxyl compound E₂.

Evidence of unlabelled oestradiol in extracts of seeds, vegetative and flowering plants was obtained using a modified radioimmunoassay (RIA) technique⁹ and combined gas chromatography-mass spectrometry (GC-MS). The GC-MS analysis¹⁰ involved continuous monitoring at the collector of the ion abundance at m/e 416 (molecular ion of the bis-trimethylsilyl derivative of oestradiol) as generated in the ion source from the GLC effluent of an SE-30 column operated at 250 °C. This process, commonly referred to as single-ion monitoring, enabled us to use the GC-MS system as a semi-specific detector for oestradiol.

This identification contrasts with the results of Kopcewicz⁵ who presented TLC evidence for oestrone in *P. vulgaris* but could not detect oestradiol in the extracts. Indeed, this is only the second report of oestradiol detected as a plant steroid, Awad¹¹ having isolated both oestrone and oestradiol from seeds of *Prunus*.

The verification of the endogenous biosynthesis of a steroid oestrogen in *P. vulgaris* opens the way to further studies of the suggested correlation between the quantitative levels of these compounds in this species and the onset of flowering⁵. Preliminary data obtained by RIA suggest that oestradiol is present at 2–10 μg kg⁻¹ fresh weight in seeds and leaves. It should also be possible to examine the overall pathway of biosynthesis of steroids in plants in order to investigate the presumed homology between plants and animals⁴. In addition, the potential for hormonal heterophyly¹² with respect to oestrogens in plants requires attention.

We thank Dr B. Cook for assistance with RIA and Professor K. Overton and J. Dalziel for radio-GLC facilities. The GC-MS instrumentation (AEI MS30) was provided by grants from the SRC, and I.J.Y. was financed by a post-graduate award from the SRC.

Direct evidence of the capacity of the XY germ cell in the mouse to become an oocyte

INDIRECT evidence of the capacity of a Y-containing germ cell to become functional oocyte in ovarian tissue of a chimaeric XX/XY female mouse has been published¹. This animal was one of two fertile XX/XY females obtained by aggregation of early morulae of the inbred strains AKR (albino) and CBA-T6 (agouti). Mated to a BALB/c (albino) male she had given birth to two litters that included one albino son, the remaining six young being agouti. Afterwards she had been retained for observation in connection with another investigation. In consequence she was more than 12 months old when her chromosomes were examined and she was found to contain both XX (CBA) and XY (AKR) cells. Only then was it realised that this implied that the egg that gave the albino son had come from a Y-bearing oocyte. Although ancillary evidence effectively excluded the possibility of erroneous recording or mixture of animals as explanations, there may have been some reluctance to accept the conclusion that a Y-bearing germ cell had become a functional oocyte. It is therefore satisfying to report here the direct observation of an XY oocyte at diakinesis in a preparation from another fertile, chimaeric XX/XY female mouse.

The animal was one of a series of chimaeras obtained by aggregation of embryos from matings chosen with another purpose in view². When breeding tests and other observations had been completed cultures were set up from tail blood of some of the animals and two females that had bred successfully were found to be XX/XY chimaeras. The one (M 9263) had an XY 'pigmented' component with a standard karyotype and an XX 'albino' component marked by a single large metacentric chromosome (Rb1 Ald); the other (M 9290) had an XX 'pigmented' component and an XY 'albino' component homozygous for Rb1 Ald. Both underwent a more detailed chromosome study that included various somatic tissues and also meiosis in oocytes, using preparations made by a modification of Tarkowski's³ method following brief *in vitro* culture⁴. One oocyte from M 9263 at diakinesis (Fig. 1) contained 19 normal bivalents, plus two univalents corresponding closely in relative size to the univalent X and Y chromosomes seen frequently in spermatocytes. Any doubt that these two univalents may have represented a deficient chromosome (not necessarily X) and its normal homologue is removed by the presence of 19 normal bivalents, and the absence of the Rb1 Ald trivalent seen in the remaining oocytes (Fig. 2).

The discovery of this XY oocyte in diakinesis, we hope,

Fig. 1 Oocyte at diakinesis from XY component of M 9263. 19 bivalents plus X and Y univalents (arrowed). Bar represents 10 nm.

Fig. 2 Oocyte at diakinesis from XX component of M 9263. 18 bivalents plus Rb1 Ald trivalent (arrowed). Bar represents 10 nm.

will remove any scepticism that may remain concerning origin of the exceptional albino son of the earlier report from a Y-bearing oocyte. The cytogenetic evidence showed that the son had received his Y chromosome from his mother and also, surprisingly, that he had the rare 41, XXY ('Klinefelter') karyotype¹. The possibility could therefore not be excluded that a chance non-disjunctional event during oogonal mitosis had given an XXY oocyte that had contributed an X and a Y chromosome to the zygote by secondary non-disjunction.

The alternative was to assume primary non-disjunction in an XY oocyte. Should the first explanation be correct, survival and maturation of the XXY oocyte may have been favoured, even made possible (in view of the presence of the Y chromosome), by the presence of the two X chromosomes, and the event could then have been unique and of trivial significance. The new observation, however, shows that an XY oocyte can at least develop to the point where its germinal vesicle is capable of resuming meiosis during the brief period (4 h) of culture *in vitro*. This normal response to culture and the normal appearance of the chromosomes, moreover, strongly suggest that the oocyte was developing naturally and that it would have been capable of completing normal maturation, including release from its follicle, transport to the oviduct and fertilisation.

The presence of univalent X and Y in the exceptional oocyte (see Fig. 1) gives a hint, and only a hint, that pairing of X and Y in oocytes may be less assured than in spermatocytes, thereby increasing the likelihood of non-disjunction and rendering more plausible the assumption of primary non-disjunction in an XY oocyte.

Relevant data from the four known fertile XX/XY females are summarised in Table 1. The 22 scorable oocyte preparations were obtained from 25 oocytes set up in culture. Breeding records and direct cytological examination together indicate actual or potential functional capacity of 173 XX oocytes and two XY oocytes. This gross disproportion may at first suggest that XY germ cells, though capable of normal function, are nevertheless at a strong disadvantage compared with XX germ cells. Further consideration, however, indicates that such a conclusion would be premature.

The literature provides records of 36 XX/XY chimaeric mice constructed by aggregation of morulae and representing balanced combinations⁵ of component strains: 21 of them were fertile males, six sterile males, three intersexes, four were sterile females, and only two were fertile females⁶⁻¹⁰. Most XX/XY chimaeras evidently develop as males and it is reasonable to suppose that the XX/XY

Table 1 Observations on fertile XX/YY female chimaeras

Mouse number	Age when killed (months)	Sex chromosomes and estimated percentage composition of soma		Offspring		Sex chromosomes of oocytes	
		Pigmented component	Albino component	Pigmented	Albino	XX	XY
9263	13	XY 2	XX 98	0	64	12	1
9290	13	XX 82	XY 18	66	0	9	0
15	15	XX 65	XY 35	6	1	} Not studied	
16	17	XX 75	XY 25	16	0		

The chimaeras were obtained by aggregation of morulae from pigmented and albino stocks. The percentage composition of the soma was estimated as the mean of estimates of proportions of mitotic cells of the two types in direct chromosome preparation from the lymphomyeloid complex, corneas and gut epithelium (mouse 9263); or from lymphomyeloid complex and corneas only (mouse 9290); or the percentage of agouti in the coat (mice 15 and 16)¹. The offspring were derived from matings to albino males. The sex chromosomes of the oocytes were identified in direct chromosome preparations.

females are those that, by chance, contained relatively few XY cells as embryos. It is therefore not surprising to find that the mean proportion of the XY component in the soma, derived from the estimates for the four individual XX/XY females (Table 1), is only 20%. If the proportion of XY cells is assumed to be the same in germ line and soma, the probabilities of drawing a single XY oocyte (or none) in random samples of 77 (chimaera 9263), and seven (chimaera 15), are given by the sums of the first two terms of the binomials $(0.98+0.02)^{77}$ and $(0.65+0.35)^7$, and are 0.54 and 0.23 respectively. Furthermore, breeding tests show that even in XX/XX and XY/XY chimaeras the germ cells are frequently derived from only one of the two components¹¹. In the series from which M 9263 and M 9290 were taken, only eight of the 15 female chimaeras had mixed progenies. Of the remaining seven, one died before tests were completed and four proved on chromosomal examination to be XX/XX, only the two animals described here being XX/XY. The lack of evidence of functional XY ova in two of the four fertile XX/XY females would not therefore be remarkable even if XX and XY oocytes had equal potential for maturation and function.

The rarity of functional XY oocytes in fertile XX/XY female chimaeras cannot therefore yet be taken to indicate that the XY germ cell is at a disadvantage of some kind when it finds itself in a potentially competitive position with XX germ cells either during early proliferation and migration in the developing embryo or later in the ovarian environment. A disadvantage would nevertheless not be surprising in view of the evidence that both X chromosomes are normally active in XX oocytes¹²⁻¹³, and that early embryos derived from XO mothers develop more slowly than those derived from XX mothers¹⁴.

The decisive demonstration that XY germ cells can become functional oocytes means that the developmental fate of the primordial XY germ cell is not irrevocably determined before its migration to the gonads is complete. Evidently the sex of a germ cell is not an autonomous property but is determined by the nature of the gonad in which it finds itself. Our demonstration provides further evidence to counter recent criticism¹⁵ of our original report.

We thank P. H. Glenister for construction of chimaeras.

The XY chromosome pair in mouse and human spermatocytes, visualised by silver staining

THE nature of the relationship between the X and Y chromosome in human spermatocytes has not been clearly explained by the extensive cytological studies of the last 50 yr (see refs 1-3 for reviews). The sex chromosomes of man and other mammals form a condensed mass (the so-called 'sex vesicle') during zygotene-pachytene in spermatocyte nuclei. Because of its density, the internal structure of the sex vesicle could not previously be studied by light microscopy. We describe here a technique which clearly stains the sex chromosomes within the condensed sex vesicle.

Testicular biopsies of C57BL/6 and BALB/c mice, and of human males were processed by the technique of Evans *et al.*⁴. The material was placed in 1% sodium citrate, teased apart with dissecting scissors to free the tubules, and left for 1 h. After centrifugation, the supernatant was gently pipetted off and the pellet fixed with a fresh mixture of 3:1 methanol:acetic acid for 30 min. The fixative was changed twice. Chromosome preparations were made by the air drying technique.

The silver staining procedure is simplified from a technique of Howell *et al.*⁵, developed to demonstrate nucleolus organiser regions on somatic chromosomes. It consists of two basic steps: (1) Air-dried preparations are treated with three or four drops of 33% aqueous AgNO₃, pH 5.5, under a coverglass for 6-10 min beneath a photoflood light at a temperature of 50-70 °C. After cooling, the AgNO₃ is washed off with deionised water and the preparation is again air dried. (2) Working at room temperature, two drops of ammoniacal silver (8 g AgNO₃ dissolved in 10 ml H₂O, then added to 15 ml concentrated NH₄OH) are placed on the chromosome preparation and immediately followed by two drops of 3% acetate-neutralised formalin. A cover glass is added. The pH of the combined fluids should be 12-13. As soon as the preparation turns a deep yellow (10-60 s) the silver solution is quickly washed off, and the slide made permanent.

After this treatment, the sex vesicle can be seen as a prominent structure, situated at the periphery of the nucleus, and frequently slightly dissociated from it (presumably by the hypotonic treatment).

In the mouse, the two sex chromosomes are seen as thin, positively stained threads, each almost symmetrically curled back on itself, the longer (presumptive X) being readily

Fig. 1 Pachytene nucleus from a male mouse. X and Y chromosomes are clearly seen within the sex vesicle; also the nucleolus-like body associated with X.

distinguished from the shorter (presumptive Y). Both ends of both chromosomes usually seem to be fixed to the periphery of the sex vesicle not very far from one another. One end of the X, and one end of the Y, are particularly

close to one another, and here the chromosomes seem to run in parallel for a short distance in what may be a parasyntaptic association. In addition to this association, the Y in many cells crosses the X again at approximately the same place along its length (see Figs 1 and 2).

At a point about one third along its length the X chromosome is quite regularly associated with a round body which looks like a nucleolus. At pachytene this sphere stains lighter than the surrounding material, although with acridine orange it looks very pale.

In man, the figure has features in common with that of the mouse, although in the early stages of meiotic prophase the sex chromosomes are curiously intertwined and although no nucleolus is evident in the vesicle. The sex bivalent is folded so that the X chromosome forms a rod with the presumptive centromere near the nuclear membrane, and the distal tip is associated with the Y chromosome. Synapsis between the long arms of both chromosomes would then be particularly easy (Fig. 3). In later stages, the bivalent looks much as it does at diakinesis, but more elongated. Generally, a third of the long arm of the X chromosome runs alongside the long arm of the Y chromosome. The X centromere and the distal part of the long arm of the Y are clearly seen, while the other bivalents are still almost indistinguishable.

Fig. 2 Sex bivalents from spermatocytes of the mouse at pachytene and interpretative diagrams. In the diagrams the X chromosomes are shown as continuous, the Y chromosomes as discontinuous.

Fig. 3 Sex bivalents (arrowed) in spermatocytes from a normal human male at pachytene.

The sex vesicle is usually densely stained, but in favourable circumstances the curled up sex bivalent has been seen within it⁶. Our observations confirm the side-by-side configuration of segments of the sex chromosomes suggested by previous work. The pictures obtained by this relatively simple light microscope technique are very similar to those previously obtained by three dimensional reconstructions of electron microscope sections³.

The question about the existence of chiasmata between the human X and Y chromosomes has not yet been resolved². After diplotene, the sex pair is seen to be joined in an end-to-end relationship, which may be a terminalised chiasma. A common end region expressed as a short synaptonemal complex is present in the mouse and the human².

Detailed studies of the sex vesicle in pachytene by the method we have described could aid the analysis of structural rearrangements of the sex chromosomes in the mouse and other mammals and might complement clinical diagnosis in males with sex chromosome aberrations or infertility (Fig. 4).

Fig. 4 Sex bivalent in a spermatocyte at pachytene from an azoospermic human male.

Simpler technique for serological detection of H-Y antigen on mouse lymphocytes

THE serological detection of the H-Y (male) antigen in the mouse has been demonstrated¹ using the cytotoxicity test against mouse spermatozoa, and that work has been confirmed² by the demonstration of H-Y on male (not female) mouse epidermal cells. There are, however, technical difficulties associated with both assays and these are hard to overcome. We report here a simplified method for the serological detection of H-Y antigen on mouse lymphocytes using *Staphylococcus aureus* (SA) as a marker. We do this in the interests of other investigators who may wish to investigate the H-Y system by a relatively simple method.

SA contains protein A, a polypeptide of molecular weight 42,000 which binds to the Fc of IgG molecules from several species³. It is linked covalently to the peptidoglycan in the cell wall of most strains of SA⁴. Kearney *et al.*⁵ have described a method of detecting membrane-associated antigens on lymphoid cells by antibody coupled to protein A of SA. We have used this procedure to detect H-Y antigen expressed on male lymph node cells.

Mice were purchased from the Jackson Laboratory. Anti-H-Y serum was produced in C57BL/6 (B6) female mice by repeated inoculation with 25×10^6 B6 male spleen cells. Serum was obtained 10 d after the seventh inoculation. Anti-H-Y activity was determined by the cytotoxicity test, with mouse spermatozoa as target cells according to the method of Goldberg *et al.*¹. The Cowan I strain of SA containing 1.7% protein A was obtained from Dr R. C. Williams Jr. It was cultured in Todd-Hewitt broth (Difco) at 37 °C and collected after an 18-h incubation on a shaker. The cells were washed three times in phosphate-buffered saline (PBS; 0.02 M PO₄; 0.15 M NaCl, pH 7.2) and then incubated for 3 h at 37 °C in PBS containing 0.5% formaldehyde. The cells were then washed four times in PBS and placed in a boiling water bath (94 °C in Albuquerque, New Mexico) for 2.5 min at a 10% (v/v) cell concentration. This stock suspension was stored at 4 °C in the presence of 0.1% NaN₃. Before use, cells were washed and resuspended in PBS.

The axillary and inguinal lymph nodes were removed from B6 mice. After mincing into a single cell suspension in Eagle's minimal essential medium (MEM, Gibco), they were washed and resuspended to a concentration of 2×10^7 cells per ml. Anti-H-Y (50 µl) serum was added to 0.25 ml of lymph node cells from male mice and incubated for 30 min at 4 °C. To test for specificity of the H-Y antiserum, lymphocytes from B6 female mice were also treated with anti-H-Y serum. A further control consisting of male lymph node cells treated with normal mouse serum was also included. After washing twice with 5 ml (20 volumes) of MEM containing 10% foetal calf serum (FCS; previously heated to 56 °C for 30 min), the cell pellet was mixed with 0.05 ml of SA suspension and incubated for 15 min at 4 °C. To reduce the background number of unattached SA, the mixture was washed three times in 5 ml of MEM, containing 20% FCS, by centrifugation at 200g for 10 min at 4 °C. After the final wash, the pellet was resuspended in 0.25 ml of MEM. Smears were prepared on microscope slides, air dried, fixed in methanol and stained by the Giemsa method. The slides were observed by light microscopy at $\times 400$ and $\times 1,000$.

A lymphocyte was counted positive if five or more SA were attached. Male lymphocytes were never less than 90%

positive. The average background of positive female lymphocytes, with unabsorbed serum, was 10%, with an upper limit of 20%. With the technique described here, we have made eight tests, in each of which male and female lymphocytes were compared. The slides were coded and read by four individuals. All male cells typed H-Y⁺ and all female cells types H-Y⁻, and all readers agreed on all positive and negative readings.

Tamoxifen is a potent 'pure' anti-oestrogen in chick oviduct

OESTROGEN responsive cells contain a specific proteinaceous macromolecule—one receptor—capable of recognising physiologically active oestrogens as well as a number of synthetic oestrogen agonists and antagonists^{1,2}. In the non-stimulated state, the majority of receptors are located in the cytoplasmic fraction of responsive cells^{3,4}, including the chick oviduct⁵. When oestrogen reaches the target cell, it binds to the cytoplasmic receptor causing its 'activation' and the translocation of the hormone-receptor complex to the nucleus. The interaction of receptor with chromatin is thought to facilitate gene transcription and the synthesis of proteins implicated in the changes characteristic of the oestrogenic response^{6,7}. Receptor is retained in the nucleus for varying periods of time depending on the concentration and nature of the oestrogen. In the rat uterus, the length of time that receptor is retained in the nucleus correlates well with a number of parameters of the hormonal response⁸. The initial translocation of receptor to the nucleus is followed by a period of cytoplasmic receptor replenishment^{3-5,9}. This process is very important as it has been implicated in the ability of cells to respond to subsequent oestrogenic stimulation^{10,11}. Anti-oestrogens prevent oestrogens from expressing their full effects on oestrogen target tissues. Recent studies have indicated that some non-steroidal anti-oestrogens (CI-628, nafoxidine and clomiphene) bind to cytoplasmic oestrogen receptor, induce the translocation of the antagonist-receptor complex to the nucleus, but fail to stimulate subsequent cytoplasmic receptor replenishment¹²⁻¹⁴. Oestrogen antagonism would be primarily due to inhibition of cytoplasmic receptor replenishment¹². Further, such a hypothesis could explain the weak oestrogenic activity of these compounds following a single injection when cytoplasmic receptor is translocated to the nucleus, and their subsequent potent anti-oestrogenic activity after serial injections when the low cytoplasmic receptor level is the limiting factor in receptor translocation¹⁵. We present here results which illustrate that this theory of anti-oestrogenic action does not hold for tamoxifen (ICI 46,474) in the chicken oviduct.

Oestrogen withdrawn (4-6 weeks) chickens^{5,16} were

injected with oestradiol benzoate 1 mg per kg body weight and/or tamoxifen 10 mg per kg. Magnum wet weight, DNA content, and cytoplasmic progesterone receptor concentration (increasing after oestrogen administration^{17,18}) were measured either 24 h after a single injection or 24 h after the last of three daily injections. All experimental procedures have been described previously^{5,18}. The simultaneous administration of oestradiol benzoate (1 mg per kg) and tamoxifen (10 mg per kg) resulted in complete abolition of the oestradiol benzoate induced responses. At the dose tested, tamoxifen alone demonstrated no oestrogenic activity (Fig. 1). Further experiments (manuscript in preparation) showed that even at a dose of 1 mg per kg, tamoxifen was capable of causing a significant ($\geq 50\%$) reduction in oestradiol benzoate induced magnum growth and cytoplasmic progesterone receptor concentration. Moreover, tamoxifen is a potent inhibitor of oestradiol induced ovalbumin synthesis, while having no detectable agonist effect of its own (Binart and Lebeau, unpublished).

Although tamoxifen did not induce any measurable oestrogenic response, it led to appreciable changes in the subcellular distribution of oestrogen receptors with the majority of receptor sites being located in the nucleus 24 h after a single injection (Fig. 2). No change in the total cellular oestrogen receptor level was observed at 24 h, in contrast to the increase after oestradiol benzoate and in agreement with the lack of oestrogenic properties of the anti-oestrogen. When the time-dependence of oestrogen receptor distribution was monitored over a 24 h period following injection of tamoxifen 10 mg per kg, it was apparent that approximately 70% of the cytoplasmic receptor was rapidly translocated to the nucleus during the first hour, and that this pattern of distribution was maintained for the entire period studied (Fig. 2a). In this respect, tamoxifen in the chick seemed to behave in a similar manner to the non-steroidal anti-oestrogens in the rat¹²⁻¹⁴, that is, long-term retention of the nuclear receptor and no (or delayed)

Fig. 1 The effect of oestradiol benzoate (E₂B) 1 mg kg⁻¹ and/or tamoxifen (Tam) 10 mg per kg on magnum wet weight (Wt), DNA content (DNA) and cytoplasmic progesterone receptor concentration (PR) 24 h after the final injection. Groups of oestrogen withdrawn chickens (4-6 animals per group) received either 3 injections at 24 h intervals (open bars) or a single injection (full bars). The data represent the mean $\pm$ SD of three groups of chickens and are presented as a percentage of values in non-injected control animals.

Fig. 2 The effect of a single injection of (a) tamoxifen (10 mg kg^{-1}) or (b) oestradiol benzoate (1 mg kg^{-1}) on the concentration of cytoplasmic (squares) and nuclear (triangles) oestrogen receptor sites during the 24 h following injection.

replenishment of cytoplasmic receptor. In contrast to the rat uterus, however, the presence of oestrogen receptor in the nuclear compartment of chick oviduct cells was not accompanied by any measurable oestrogenic response.

Oestradiol benzoate caused a similar degree of translocation of cytoplasmic receptor to the nucleus during the first hour (Fig. 2b), but nuclear receptor was gradually depleted after 12 h and had fallen to approximately 140% of control values by 24 h. Cytoplasmic receptor levels were replenished and had reached 150% of control by 24 h. At this time, total cellular oestrogen receptor levels had increased to about 160% of their pre-incubation level indicating oestrogen-induced synthesis of new oestrogen receptor. This pattern of receptor subcellular redistribution and synthesis was accompanied by a significant hormonal response (Fig. 1).

These results indicate that a number of currently held theories of the mechanism of action of anti-oestrogenic compounds require re-evaluation. The anti-oestrogenic activity of all non-steroidal anti-oestrogens of the triphenyl-ethylene type cannot be explained simply by their inability to stimulate cytoplasmic receptor replenishment as has been suggested previously¹². Our results show that tamoxifen in the chick oviduct is anti-oestrogenic after a single injection when cytoplasmic receptor levels are not a limiting factor in the amount of receptor translocated to the nuclear compartment. In addition the receptor which was translocated from the cytoplasm to the nucleus was unable to initiate any measurable oestrogenic response. This observation implies that the mere presence of high concentrations of oestrogen receptor in the nuclear compartment is not sufficient for hormone action and suggests, as theoretically more satisfactory, that the ligand plays an important role in determining the final activity of the ligand-nuclear receptor complex. Moreover, these results add support to the theory that there are different populations of nuclear 'acceptor' sites, some of which are biologically inactive^{1,19}. Our data, however, do not support the hypothesis²⁰ that KCl-resistant nuclear sites²¹ designate the specific 'acceptor' sites involved in the expression of maximal oestrogen-induced growth since we were unable to demonstrate any difference between oestradiol benzoate and tamoxifen treated animals with respect to the proportion of nuclear receptor sites which could be extracted with 0.5 M NaCl (manuscript in preparation).

Finally, since tamoxifen, like nafoxidine and clomiphene, is an anti-oestrogen and a weak oestrogen when tested in rodents^{22,23}, some of the discrepancies between the present data and those reported previously for rat uterine system

may be due to species differences in the mechanism of action of these compounds.

We thank Dr A. L. Walpole of ICI for the tamoxifen (Ici 46, 474). This work was supported by the Délégation Générale à la Recherche Scientifique et Technique, the Ford Foundation, and Roussel-Uclaf. Induction of human follicle-stimulating hormone in HeLa cells by sodium butyrate

THE ectopic production of polypeptide hormones by tumours derived from tissues that normally do not synthesise these proteins provides a means for investigating regulation of gene expression. All of the hormones ectopically synthesised by non-endocrine tumours are polypeptides or prostaglandins; however, pituitary gonadotropin production by neoplasm as opposed to chorionic gonadotropins is apparently very rare¹. Only one patient has been reported in which a bronchiogenic carcinoma produced follicle-stimulating hormone (FSH) and luteinising hormone (LH)

Table 1 Enhancement of FSH production by butyrate in HeLa cells

Subline	β -subunit of FSH antiserum FSH(ng) secreted* by 10^6 cells			Complete FSH antiserum FSH(mIU) $\dagger$ secreted* by 10^6 cells		
	Mean	Range	Proportional increase	Mean	Range	Proportional increase
HeLa ₆₅ , control	2.9	0.3–4.8	1	1.7	1.3–2.1	1

HeLa ₇₁ , control	116.6	65.9–204.5	1	2.7	2.5–2.8	1
HeLa ₇₁ , 1 mM butyrate	731.7	609.8–975.6	6	16.0	14.6–17.1	6
HeLa ₇₁ , 5 mM butyrate	17,555.5	9,333.3–28,333.3	151	313.0	293.3–333.3	116

HeLa₆₅ and HeLa₇₁ cells were cultured with and without sodium butyrate for 68 h in Waymouth's medium with 10% foetal calf serum and antibiotics (penicillin 30 μ g; streptomycin 50 μ g and kanamycin 30 μ g ml⁻¹). Methods of subculturing, collecting and preparing cells for assays were as before⁴. The media and ultrasonicates of cells were tested for FSH by radioimmunoassay (RIA) using ¹²⁵I-FSH as the tracer antigen^{8–10}. Radiolabelled iodinated FSH was prepared by the Chloramine-T method and purified on polyacrylamide gel. To minimise cross-reactions with other closely related glycopolypeptides, one antiserum was raised in rabbits against the β -subunit of FSH extracted and purified from fresh frozen human pituitary glands (from Diagnostic Biochem). A second antiserum was prepared against highly purified complete human pituitary FSH (Institute of Bioendocrinology, Montreal). Radioactive antigen-antibody complexes were isolated by double-antibody precipitation technique⁸ using as the second precipitant antibody, an anti-rabbit γ globulin prepared in goats with antiserum against the β subunit and an anti-rabbit γ globulin prepared in sheep with antiserum against complete FSH. Radiolabelled precipitate was collected by centrifugation at 6,000g at 2°C and counted in a Beckman Biogamma II spectrometer. The percentage of binding of radioactive ¹²⁵I-FSH by antiserum against the β subunit of FSH was plotted against pg concentrations of purified human pituitary FSH as the standard on logit-log graph paper. The limit of sensitivity of the assay was 50 pg. The percentage binding of radioactive ¹²⁵I-FSH by antiserum against complete FSH was plotted against mIU of Second International Reference Preparation of Human Menopausal urine Gonadotropin (2nd IRP HMG) as the standard. The limit of sensitivity of the assay was 0.16 mIU. Concentrations in unknown samples were determined either from the linear standard logit-log plots or from sigmoid calibration curves on semi-logarithmic scales. Apparent differences in concentrations of FSH as measured by the two antisera are probably the result of differences in the standards used and the higher sensitivity of the radioimmunoassay with β -FSH antiserum. The results presented in the table are means of duplicate assays on three separate experiments carried out at different times. A standard of authentic FSH at seven different dilutions and a sample of human serum with a known concentration of FSH were assayed concurrently with unknown samples to ensure accuracy and reproducibility of the technique. As measured by RIA, TSH and human placental lactogen (HPL) could not be detected nor induced by sodium butyrate in these HeLa sublines.

*As measured in the medium.

$\dagger$ 1 mIU equivalent to 35ng of LER 907 FSH standard (NIH).

(ref. 2). Glycopeptide hormones—FSH, LH, thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (HCG)—are composed of two dissimilar subunits: an α subunit that is common to all the glycopeptide gonadotropic hormones and a β subunit unique for each hormone that confers biological specificity³. It has been shown that HeLa cells, derived over 25 yr ago from a carcinoma of the cervix, secrete HCG (refs 4,5) and the free α subunit of glycopeptide hormones⁶. Synthesis of HCG (ref. 4) and the α subunit⁵ is markedly increased by growth in medium with sodium butyrate. We report that HeLa cells also produce pituitary FSH which is induced by butyrate. The surprising synthesis of FSH by a non-pituitary cell has required validation of the radioimmunoassay (RIA) to exclude cross-reaction with other gonadotropic hormones.

Two different antisera were used; one was prepared against highly purified human pituitary β subunit of FSH and the other against the complete hormone. The anti- β FSH serum had the following cross-reactivities: FSH 100%, HCG <1%, LH <5%, TSH <2% and growth hormone (GH) <1%. A second antiserum prepared against intact human pituitary FSH had the following cross-reactivities: <0.01% human serum albumin; <2% TSH and <0.01% with LH, HCG and GH. The tracer antigen used in the

radioimmunoassay was highly purified human pituitary ¹²⁵I labelled FSH.

Table 1 shows that two well-characterised clonal lines of HeLa cells, HeLa₆₅ and HeLa₇₁ (ref. 7), produce different basal levels of FSH. Similar differences between HeLa sublines have been observed with α chain^{5,6} and HCG production⁷ and may reflect functional alterations related to the well-known karyotypic differences between these sublines. Growth of replicate cultures of HeLa₆₅ and HeLa₇₁ cells with 1 and 5 mM butyrate caused a marked increase in FSH production (Table 1). HeLa₇₁ cells produce much more FSH in the basal and butyrate-induced state than HeLa₆₅. Dilution curves for immunoreactive substances in HeLa cell media were similar to those of authentic FSH. As shown in Table 1, the correlation of FSH values obtained by β -FSH and complete FSH assays are reasonably close except for HeLa₆₅ control where low concentrations of FSH may affect the accuracy of the assay. Differences in the apparent concentration of FSH as measured by two different antisera are probably due to the characteristics of the standards and to the greater sensitivity of β -FSH assay. Table 2 compares intracellular FSH with that secreted into the medium during 48 h of growth in medium without and with sodium butyrate. Approximately 90% of

Table 2 Comparison of intra- and extracellular levels of FSH in HeLa cells grown without and with sodium butyrate

Subline	FSH levels			
	Intracellular ng per 10^6 cells	Proportional increase	Extracellular ng per 10^6 cells	Proportional increase
HeLa ₆₅ , control, 48 h	0.2	1	4.6	1
HeLa ₆₅ , 5mM butyrate, 48 h	3.8	19	47.1	10.2
HeLa ₇₁ , control, 48 h	12.2	1	391.3	1
HeLa ₇₁ , 5mM butyrate, 48 h	66.7	5.5	1,666.6	4.3

FSH was measured by RIA as described in Table 1. The values are means of quadruplicates that varied by less than 15%.

Table 3 Induction of FSH in HeLa₆₅ cells by hydroxyurea and its synergism with sodium butyrate

Concentration of hydroxyurea (mM)	FSH levels in HeLa ₆₅ cultures			
	Grown for 96 h without butyrate		Grown for 96 h with 1 mM butyrate	
	ng per 10 ⁶ cells	Proportional increase	ng per 10 ⁶ cells	Proportional increase
0.00	23.8	1.0	69.7	2.9
0.01	33.1	1.4	115.1	4.8
0.05	36.0	1.5	125.0	5.3
0.25	80.8	3.4	310.3	13.0
1.00	416.7	17.5	736.8	31.0

FSH secreted in medium was determined by RIA as described in Table 1. The values are means of duplicates that varied by less than 10%.

the hormone synthesised is secreted into medium. Differences in the base-level production of FSH and the proportional increase mediated by butyrate as shown in Tables 1, 2 and 3, may be related to confluence of the culture and to the duration of growth with inducer.

Sodium butyrate has been shown to inhibit DNA synthesis in HeLa₆₅ cells¹¹. Recent studies have shown that other well-characterised inhibitors of DNA synthesis that are used as anti-neoplastic agents—hydroxyurea, methotrexate, and 1- β -D-arabinofuranosylcytosine—also increase HCG synthesis¹¹. For these reasons hydroxyurea which is a specific inhibitor of DNA but not RNA synthesis in HeLa₆₅ cells was studied for its capacity to induce FSH synthesis in HeLa₆₅ cells and to potentiate the effects of sodium butyrate (Table 3). Hydroxyurea stimulated FSH production and was synergistic to sodium butyrate (Table 3). Neither butyrate nor hydroxyurea when added to the radioimmunoassay affected measurements of FSH.

HeLa cells produce several proteins normally found in trophoblasts; these include the placental forms of alkaline phosphatase^{12,13}, ferritin^{14,15}, aldolase¹⁶, α -chains of glycopeptide hormones^{3,6}, and HCG^{4,5}. The availability of specific antisera against the human pituitary β subunit and complete FSH permitted measurement of this glycopeptide in the presence of excess α chains and HCG. The production of a presumptive pituitary gonadotropin by a non-pituitary cell is unexpected and suggests that the genome of HeLa cells is derepressed for highly differentiated gene products as well as oncofetal proteins. Butyrate, certain other aliphatic monocarboxylates and some antineoplastic drugs that inhibit DNA but not RNA synthesis, increase the activity of oncofetal alkaline phosphatase¹⁷ and HCG synthesis^{4,11}. Our finding that butyrate and hydroxyurea also stimulate FSH production suggests that inhibition of DNA synthesis or cell multiplication may have a role in modulating gene expression. Little is known about the mechanism by which specialised synthetic programmes are coupled to inhibition of DNA synthesis. The acquisition of a differentiated phenotype, however, is preceded by inhibition of cell division in several embryonic tissues^{18,19}. Studies on regulation of glycopeptide hormone production in HeLa cells may help elucidate aspects of gene expression in normal as well as malignant cells.

Parallel expression of new idiotypes on T and B cells

THE structural nature of the antigen receptor on thymus-derived (T) cells is as yet unresolved^{1–4}. It has been clearly demonstrated that antigen receptors on bone marrow-derived (B) cells are immunoglobulin (Ig) molecules which are similar to the antibodies secreted by their progeny^{5–7}. This is further reflected in the presence of common variable region determinants present on Ig receptors and on antibodies produced by B cells belonging to the same clone^{8,9}. These variable region determinants are called idiotypes¹⁰. We report here the use of anti-idiotypic antibodies to determine whether receptors on T and B cells specific for the hapten phosphorylcholine (PC) share idiotypic determinants. The majority of PC-specific B cells in BALB/c mice have receptors bearing an idiotypic characteristic of the myeloma protein TEPC 15 (T15) (ref. 8). To determine whether receptors on PC-specific T cells also reflect this 'idiotypic homogeneity', we have induced PC-specific helper T cells and attempted to inhibit their activity using anti-T15 antibodies. Our results indicate that receptors on PC-specific T and B cells share similar idiotypes.

To obtain hapten-specific T cells, we immunised BALB/c mice with either PC-conjugated MOPC 315 (PC₃-M315) (ref. 11) or dinitrophenyl (DNP)-conjugated mouse immunoglobulins⁷ (DNP₉-MIg) as previously described¹². At least 6 weeks after priming, splenic T cells were purified by nylon wool filtration¹³. Bovine serum albumin (BSA)-primed B cells were obtained from BALB/c mice immunised as previously described¹². At least 6 weeks after priming, spleen cells from these mice were treated with anti-Thy 1.2 serum and complement.

The PC-M315 and DNP-MIg-primed splenic T cell populations were assayed for helper activity in an adoptive transfer system with BSA-primed B cells. Either 50 μ g of aqueous PC-conjugated BSA (PC₂₈-BSA) (ref. 11) or 50 μ g of aqueous DNP-conjugated BSA (DNP₄₅-BSA) (ref. 7) was given intravenously with the cell inoculum. The mice

Table 1 Demonstration of PC- and DNP-specific helper T cells

—	15	—	PC ₂₈ -BSA	2 (1-3)
—	—	15	PC ₂₈ -BSA	0.5 (0.4-0.6)
10	—	—	DNP ₄₅ -BSA	13 (10-17)
—	15	—	DNP ₄₅ -BSA	2 (1-3)
—	—	15	DNP ₄₅ -BSA	0.5 (0.3-0.6)
10	15	—	PC ₂₈ -BSA	297 (266-331)
10	15	—	DNP ₄₅ -BSA	33 (25-43)
10	—	15	DNP ₄₅ -BSA	185 (163-210)
10	—	15	PC ₂₈ -BSA	36 (31-42)

*Cells were transferred into 600 R irradiated BALB/c mice. Animals received 50 μ g of aqueous antigen simultaneously with the cells and were killed on day 8 post cell transfer.

†Spleen cells from BSA-primed mice were treated with anti-Thy 1.2 antiserum and complement.

‡Mice were primed with either PC₂₈-M315 or DNP₄₅-MIg. T cells were purified by nylon wool filtration¹³. Both T cell populations contained > 90% T cells and 1% Ig bearing cells as assessed by immunofluorescent staining.

§Geometric mean of the responses of four or five animals per group. Numbers in parenthesis represent one standard error about the mean. The direct anti-BSA PFC response in all groups was less than 5% of the total response. Indirect anti-BSA PFC were developed using a polyvalent rabbit anti-mouse immunoglobulin antiserum.

were killed 8 d later and their spleens assayed for anti-BSA plaque-forming cells¹⁴ (PFC) using BSA-conjugated sheep erythrocytes¹⁵ as indicator cells.

Transfer of 15×10^6 PC-primed T cells together with 10×10^6 BSA-primed B cells and PC₂₈-BSA, resulted in a response of 29,700 indirect anti-BSA PFC per spleen (Table 1). This response is 19-fold higher than the background response calculated by summing the responses obtained on transfer of the same cell populations separately, that is, 1,600 anti-BSA PFC. When the same cell populations were transferred with DNP₄₅-BSA as antigen, the resulting anti-BSA PFC response was only two-fold above background (Table 1). Similarly, transfer of 15×10^6 DNP-primed T cells with 10×10^6 BSA-primed B cells resulted in an anti-BSA PFC response 12-fold above background with DNP₄₅-BSA as antigen and only two-fold higher than background when PC₂₈-BSA was used as antigen (Table 1).

To assess whether the helper activity of PC-specific T cells could be inhibited with anti-T15 antibodies, irradiated BALB/c mice were injected with anti-T15 antibodies 24 h before and at the time of, transfer of PC-primed T cells and BSA-primed B cells. Antigen (50 μ g of PC₂₈-BSA) was given 16 h after cell transfer. The animals were killed 8 d after antigen administration and their spleens assayed for anti-BSA PFC.

The data in Table 2 show that anti-T15 antibodies com-

pletely inhibit PC-specific helper activity. When 10×10^6 PC-primed T cells were transferred with 5×10^6 BSA-primed B cells and PC₂₈-BSA into conventional irradiated recipients, the resulting anti-BSA PFC response was six-fold higher than background, that is, 9,100 against 1,500 anti-BSA PFC per spleen respectively. Treatment of the recipients with anti-T15 antibodies inhibited the anti-BSA PFC response to less than 1% of the control response, that is, 1,400 anti-BSA PFC per spleen. The specificity of inhibition was established by assessing the effect of anti-T15 antibodies on the expression of DNP-specific helper activity. When 10×10^6 DNP-primed T cells were transferred with 5×10^6 BSA-primed B cells and DNP₄₅-BSA, the resulting anti-BSA PFC response was sevenfold above background, that is, 8,600 against 1,200 anti-BSA PFC spleen. Treatment of DNP-primed T cell recipients with anti-T15 antibodies did not significantly affect the anti-BSA PFC response which remained ninefold higher than background (Table 2).

The irradiated recipients used in these experiments contained high levels of T15-bearing Ig with demonstrable anti-PC activity¹⁶. It is conceivable that on transfer into irradiated recipients, PC-specific T cells bind PC₂₈-BSA which in turn picks up circulating T15 positive anti-PC antibodies. Thus, PC-specific T cells obtained from conventional BALB/c mice could bear T15-negative receptors and their helper activity might still be inhibited by anti-T15

Table 2 Inhibition of PC-specific helper activity with anti-T15 antibodies

*Cells were transferred intravenously into 350 R irradiated BALB/c mice. Animals received 50 μ g of aqueous antigen intravenously, 16 h after cell transfer, and were killed on day 8 post antigen administration.

†See legend for Table 1.

‡See legend for Table 1.

§0.2 ml of a 1/2 dilution of A/J anti-T15 antiserum was administered intraperitoneally 16 h prior to, and at the time of, cell transfer. The idiotype specificity of this antiserum has been reported elsewhere^{17,18}.

¶Geometric means of the responses of three to six animals per group (all groups with T+B cells contained six animals). The direct anti-BSA PFC response in all groups was less than 5% of the total response. Indirect anti-BSA PFC were developed using a polyvalent rabbit anti-mouse immunoglobulin antiserum.

**% of control response was calculated as follows: Inhibition of PC-specific helper activity: $[14 - (8 + 7)]/[91 - (8 + 7)]$ where (8 + 7) is the background anti-BSA PFC response obtained on transfer of T or B cells alone with PC₂₈-BSA. Similarly, inhibition of DNP-specific helper activity $[106 - (9 + 3)]/[86 - (9 + 3)]$.

antibodies.

To test this possibility we took advantage of the observation that receptors on PC-specific precursor B cells in BALB/c mice neonatally suppressed with anti-T15 antibodies bear T15-negative idiotypes^{17,18}. If neonatal idiotype suppression induces a parallel change in receptors expressed by PC-specific T cells, their helper activity should not be inhibited by anti-T15 antibodies, unless they adsorb T15-positive anti-PC antibodies naturally present in the conventional BALB/c recipients. The results in Table 3 show that when either 7.5×10^6 or 3.8×10^6 PC-primed T cells from T15-positive donors were transferred with 5×10^6 BSA-primed B cells, the resulting anti-BSA PFC responses obtained were sixfold higher than background. Again, these responses were completely abolished by treatment of recipients with anti-T15 antibodies, that is, less than 1% of the control response (Table 3). Comparable helper activity was obtained on transfer of 10×10^6 PC-primed T cells from T15-negative donors. Treatment of recipients with anti-T15 antibodies, however, did not significantly affect the anti-BSA PFC response which remained sevenfold above background, that is, 122% of the control response (Table 3). We conclude that the target of anti-T15 antibodies is not a molecule passively adsorbed on the T cell surface either directly or through antigen bridge; it is the functional receptor present on PC-specific T cells which bears the T15 idiotype.

These studies demonstrate a parallel behaviour between antigen receptors on PC-specific T and B cells. As has been previously shown, antibodies directed towards the T15 idiotype specifically inhibit the function of PC-specific B cells from T15-positive BALB/c mice⁸. Similarly, the helper activity of PC-specific T cells from T15 positive mice is also inhibited by anti-T15 antibodies. Furthermore, PC-specific T and B cells from neonatally suppressed mice bear receptors which lack the T15 idiotype. These results suggest (1) that the T15 idiotype is present in the repertoire of PC-specific T and B cells and (2) that neonatal suppression of this idiotype induces the expression of T15-negative receptors in both lymphocyte lineages.

Consistent with these findings is the recent work of Binz and Wigzell which demonstrated that anti-idiotypic antibodies prepared against alloantibodies specifically removed the reactivity of T cells to the same alloantigen¹⁹. In addition, Eichmann and Rajewsky²⁰ and Black *et al.*²¹ demonstrated that anti-idiotypic antibodies were able to

induce priming of both B and T cells with specificity for the same antigen. In addition to the present report, these results strongly suggest that the specificity of antigen recognition by B and T cells is very similar and that this specificity is imparted by structurally similar molecules. It has been reported, however, that T cells contain and secrete antigen-specific factors bearing markers which are *Ir* gene products^{22,23}. In addition, products of the major histocompatibility complex restrict the function of T lymphocytes of any specificity²⁴⁻²⁷. It is possible, therefore, that the V-region structures of receptors on T and B cells specific for the same antigen, bear similar idiotypes associated with structurally different molecules.

Failure to demonstrate allotype-specific helper cells for antibody production in the rat

THE way in which the immune response is regulated is poorly understood but network theories, based on idio-anti-idiotypic interactions have been widely discussed¹. It has been suggested^{2,3} that in addition to the idiotypic-based network an allotype network also exists. This hypothesis rests on the demonstration³ that in a particular mouse strain, carrier-primed T cells from Ig 1-a homozygotes collaborated in a secondary anti-DNP (dinitrophenol) response with Ig 1-a allotype, but not Ig 1-b allotype, B cells from DNP-primed 1-a/1-b heterozygotes. In attempting to understand the regulation of the immune response it is clearly essential to establish whether the heavy chain allotype specificity of helper T cells shown by these experiments is common to all allotypes and is not a particular feature of the system studied. Here we describe experiments in which we were unable to demonstrate allotype-specific helper cells for antibody production in the rat.

T cells and DNP/BGG were injected intravenously into irradiated PVG/c homozygotes and the number of 1-a allotype anti-DNP plaque-forming cells per recipient spleen was determined using an autoradiographic plaque assay⁷.

The results show that in the absence of helper T cells hapten-primed B cells on transfer to irradiated recipients respond poorly to challenge with the priming antigen (Table 1). In contrast a greatly augmented B cell response is obtained when carrier-primed T cells are provided even if these derive from donors of the opposite light chain allotype. (The variation between the magnitude of augmentation in the three experiments is not statistically significant being largely a reflection of the wide variation in the small response produced by the purified B cell populations transferred.) Thus the data give no indication of allotype specificity of T cell help in this system. Because the light chain allotype is present on all classes of rat immunoglobulin the results do not exclude the possibility that allotype-specific helper cells exist for some classes but not others. Nor is it possible to rule out the existence of a cell type that regulates the expression of the two light chain allotypes in 1-a/1-b heterozygotes. It is clear, however, that in the rat carrier-primed T cells and hapten-primed B

*PVG/c TDL depleted of B cells from rats primed with DNP₂₉BGG 7-12 weeks previously.

†B cells selected by FACS from TDL of DNP₂₉BGG primed (PVG/1-a $\times$ PVG/c)_{F1} (first two experiments) or PVG/1-a homozygote (third experiment) rats.

‡Recipients were PVG/c rats given 500 rad (first two experiments) or 660 rad (third experiment) 6 h before cell transfer and challenge.

§Collaborative increase refers to the factor by which the 1-a PFC response is augmented by the addition of the carrier-primed T cells.

To investigate the generality of the findings of Herzenberg *et al.*³ we examined the allotype specificity of helper T cells using the rat light chain allotype marker⁴. B and T cells from appropriate donors, primed several weeks earlier with DNP-bovine γ globulin (DNP-BGG), were injected intravenously together with DNP-BGG into irradiated recipients. The splenic anti-DNP plaque-forming cell response was assayed 1 week later. Thoracic duct lymphocytes (TDL) from PVG/1-a and (PVG/1-a $\times$ PVG/c)_{F1} rats were used as a source of B cells. PVG/1-a is a new strain, congenic with PVG/c, but carrying the 1-a light chain allotype. Heterozygotes were obtained from the sixteenth backcross and homozygotes from an incross of this generation. T cells were obtained from TDL of PVG/c homozygotes. B and T cell donors were primed intraperitoneally with alum-precipitated DNP-BGG and 2×10^6 Pertussis organisms 6-12 weeks before use. B cells were labelled by incubation with rabbit F(ab')₂-anti-rat Fab followed by fluorescenated horse-anti-rabbit Fab and isolated using a fluorescence-activated cell sorter⁵. T cells were purified by rosetting TDL with rabbit-anti-rat F(ab')₂ coated sheep red blood cells and subsequent fractionation on an Isopaque-Ficoll gradient⁶. Various mixtures (see Table 1) of B cells,

cells derived from donors of different allotype can collaborate efficiently.

Elson and Taylor⁸ using the same allotypic marker as Herzenberg *et al.*³, but with a different congenic strain combination, found no evidence of allotype restriction of helper T cells. These findings taken together with our own suggest that the contrary findings of Herzenberg *et al.* may be dependent in some way on the particular mouse strain used by these workers.

We thank Dr S. V. Hunt for the gift of rats of the new strain developed by him, Dr A. F. Williams for immunoabsorbent purified antibodies, Miss L. Hackfath for technical assistance and to Mrs J. Shepherd for typing the manuscript.

T-cell mediated immunity towards antigen(s) on isologous erythrocytes

SPLEENS of normal mice contain large numbers of cells which produce antibody against antigenic determinants on their own erythrocytes^{1,2}. To demonstrate this autoimmune response, the mouse erythrocytes (MRBC) must be treated with proteolytic enzymes, such as trypsin or bromelain, in order to reveal hidden autoantigen(s)². Treatment of mice with anti-lymphocyte serum (ALS) causes a 20-fold rise in the number of cells producing antibody to bromelain-treated mouse erythrocytes (BrMRBC) (ref. 2). Based on this observation, Cunningham has proposed that the number of cells making anti-BrMRBC antibody is controlled by an active, ongoing, T-cell induced suppression³. We report here that the culturing of normal mouse spleen cells *in vitro* not only allows the development of cells producing antibody to BrMRBCs, but also T cells which mediate, on transfer, delayed-type hypersensitivity (DTH).

Normal C57B1/6J (6–8-week-old) mouse spleen cells were cultured in Marbrook chambers⁴ at a concentration of $1.5 \times 10^7 \text{ ml}^{-1}$ in CMRL 1066 medium, supplemented with 10 ml l^{-1} each of 100-times concentrated MEM non-essential amino acids, L-glutamine, sodium pyruvate and 17% heat-inactivated foetal calf serum. The preparation of BrMRBC and the plaque-forming cell (PFC) assays were carried out as described by Cunningham¹. The separation of immunoglobulin-bearing cells, the transfer of cells into the footpads of mice, and the measurement of DTH reactions have been described in detail elsewhere^{5,6}.

When suspensions of normal spleen cells are cultured *in vitro*, a substantial anti-BrMRBC PFC response develops within 2 d (Table 1). The cultured spleen cells also induce DTH reactions when they are injected with BrMRBC into the footpads of normal mice (Table 1). In contrast to the antibody response, which peaks at day 2, the largest DTH reactions are obtained with cells taken after 4 d in culture and at a time when the antibody response is declining.

The T-cell dependence of the DTH reaction was demonstrated by treating cultured spleen cells with anti-Thy 1.2 serum and complement. Whereas untreated cultured spleen cells or cells treated with normal serum and complement induced large DTH reactions, cells treated with anti-Thy 1.2 serum and complement produced only a background footpad swelling (Table 2). Furthermore, depleting cultured

None	—	4.3 ± 0.21
Anti-Thy 1.2 + C	+	5.0 ± 0.22
Normal serum + C	+	17.5 ± 1.7
Depletion of Ig ⁺ cells	+	18.0 ± 0.8

*Spleen cells were cultured for 4 d, collected, washed and the red cells and dead cells removed by centrifugation on Isopaque/Ficoll¹⁸. Depletion of immunoglobulin-bearing cells and treatment with anti-Thy 1.2 serum are described in detail elsewhere^{5,6}. The efficiency of depleting Ig-bearing cells has been shown⁶ to be $> 97\%$. 10^7 cultured spleen cells with 10^8 BrMRBC were injected in volumes of $15 \mu\text{l}$ into the footpads of normal mice. The increase in footpad swelling is expressed in units of $0.01 \text{ mm} \pm \text{s.e.}$ Background footpad swellings ranging of 3.5–4.5 were caused by the trauma of injection.

spleen cells of immunoglobulin-bearing cells before cell transfer did not affect the level of DTH obtained (Table 2). The specificity of the DTH reactions was studied by transferring, into the footpads of normal mice, mixtures of cultured cells and various antigens (Table 3). Only with BrMRBC, sheep red blood cells (SRBC) or bromelain-treated SRBC, but not with several other antigens tested, including untreated MRBC (Table 3), were DTH reactions elicited BrMRBC and SRBC also cross react at the antibody level⁷.

These findings raise the question of how this cell-mediated autoimmune response is maintained *in vivo* at a relatively low level. Cunningham³ has proposed that suppressor T cells control the number of PFC against BrMRBC. A similar mechanism may also control the T-cell mediated immunity (CMI). This view is supported by our findings that suppressor T cells are induced with the establishment

of different, and opposing, types of immunity. Thus, T cells induced under conditions of humoral immunity can suppress CMI responses⁸, whilst CMI cells can repress the induction of humoral immunity⁹. BrMRBC antigens may induce a balanced state of CMI and IgM antibody with different populations of suppressor T cells controlling each type of immunity. If these postulates are correct, then manipulations which suppress CMI should also enhance the humoral immune response to BrMRBC. Thus, for

example, administration of ALS, which is known to selectively suppress CMI in sensitised animals¹⁰, also causes an increase in the number of PFC to BrMRBC².

Numerous other studies have shown that a wide range of self-antigens exist which are hidden on intact cells¹¹⁻¹³. Degenerating or dead cells may reveal these cryptic antigens which then stimulate both humoral and CMI responses. This autoimmunity seems harmless and may, in fact, be beneficial in removing dying or dead cells.

Furthermore, it is possible that such autoimmune responses may act as an immune surveillance mechanism that prevents the development of 'abnormal' cells such as tumour cells. Normal cells would be safe from immune attack because the self-antigens are hidden. An 'abnormal' cell that has an altered cell membrane may, however, have these cryptic sites exposed resulting in their immune destruction. Such an immune surveillance mechanism has the advantage that the immune response is primed and therefore need not adapt to new antigens on the tumour cells. Many naturally-occurring antibodies^{14,15} and cytotoxic cells^{16,17} specific to spontaneous or carcinogen-induced tumours have been found in normal mice. The antigens, against which this natural immunity is directed, have not been identified. Nonetheless, the wide-ranging differences that are known to exist between normal and tumour cell membranes are compatible with the view that natural immunity may be directed against normally hidden self-antigens that have become exposed on the tumour cells.

Uptake of nucleosides in density-inhibited cultures of 3T3 cells

AN increase in the rate of nucleoside incorporation into acid-soluble pools is one of the earliest events seen when fibroblasts arrested in the G₁/G₀ or A state¹ are stimulated to grow by the addition of serum²⁻⁵. The stimulation of uridine uptake is preceded by a lag phase of several

minutes⁶ and is not prevented by inhibitors of protein synthesis⁷. The uptake of nucleosides by mammalian cells seems to proceed in two steps: (1) the nucleosides are transferred rapidly across the plasma membrane by a facilitated diffusion mechanism⁸ and (2) the intracellular nucleosides are phosphorylated by specific nucleoside kinases and the nucleosides formed are trapped intra-

Fig. 1a, Uptake of labelled uridine by 3T3 cells as a function of time at 37 °C, in cultures previously activated by exposure to 10% foetal calf serum for 30 min, (circles) or in quiescent cells, exposed only to a serum-free medium (squares). Swiss mouse 3T3 cells¹⁴, propagated as previously described¹⁵, were subcultured into 30-mm Nunc dishes in 6% foetal calf serum; medium was changed at 3 d. Uptake activity was always assayed on confluent cells 12-15 d later. Uptake was measured by adding at zero time about 2 ml of Dulbecco modified minimal Eagles' medium (DME) containing 1.5 μM uridine, labelled radioactively as 5-³H-uridine at 1.67 Ci mmol⁻¹. At the times indicated on the abscissa, the medium was removed rapidly and the dishes were washed six times with ice-cold 0.14 M NaCl and the cultures were extracted with 1 ml of 5% trichloroacetic acid at 4 °C for 20 min. Acid-soluble pools (0.9 ml) were removed for scintillation counting with a Triton-toluene solution of phosphor. Samples for the zero-time values received the same medium and radioactivity, with the exception that it contained 1 μM NBMI, for about 2 s, before washing six times with an ice-cold solution of 1 μM NBMI in saline. The results are expressed on the ordinate as c.p.m. per dish from which the zero-time values of 281 ± 62 (s.e.m., four determinations) c.p.m. per dish for the serum-stimulated cultures, and 279 ± 55 (s.e.m., four determinations) c.p.m. per dish for the non-stimulated cultures, have been subtracted. **b**, Uptake of labelled cytosine-β-D-arabino- side as a function of time at 37 °C into 3T3 cells stimulated by serum (circles) or into non-stimulated cells (squares). Uptake was measured as for Fig. 1a, except that 5-³H-cytosine-β-D-arabino- side was at specific activity 0.5 Ci mmol⁻¹ and concentration 5 μM. The zero-time values were 89 ± 2 (s.e.m., three determinations) c.p.m. per dish for the serum-stimulated cells and 54 ± 8 (s.d. two determinations) c.p.m. per dish for the non-stimulated cultures.

cellularly⁹. Although the regulation of nucleoside uptake has been studied in some detail³⁻⁷, it is not known which of these two steps is activated by growth-promoting agents. We have investigated which step of nucleoside uptake is stimulated by serum in density-inhibited cultures of 3T3 cells. The results indicate that phosphorylation is the rate-limiting step in nucleoside uptake by quiescent cells. Growth stimulation by serum enhances the rate of phosphorylation, but apparently not that of transport.

Figure 1a shows the time course of uridine uptake by cultures that were exposed to serum for 30 min and therefore have a fully stimulated uptake⁶ compared with cultures shifted to synthetic medium alone (non-stimulated cultures). While the time course is linear in serum-activated cells, the pattern is drastically different in the non-stimulated cultures. For the first 4 or 5 s both sets display no apparent difference in uptake while afterwards the curve depicting the uptake by non-stimulated cultures levels off sharply. These results suggest that the initial rate of uridine transport is not substantially different in serum-stimulated and non-stimulated cultures, but that intracellular trapping by the kinase is much less efficient in resting cells. We also measured the time-course of uptake of cytosine- β -D-arabinoside, a nucleoside which is transported

across the cell membrane¹⁰ partly by the uridine 'carrier' system (personal communication from Z. I. Cabantchik and Y. Eilam) but is phosphorylated by deoxycytidine kinase rather than by uridine kinase^{11,12}. Figure 1b shows that the initial velocity of entry of cytosine- β -D-arabinoside into serum-stimulated cells does not differ from that of the controls. This experiment reinforces the conclusion that (nucleosides are transferred rapidly across the cell membrane of mammalian cells whether they are resting or stimulated to grow.

If the biphasic shape of the uptake curve of the non-stimulated cultures shown in Fig. 1a results from a rapid transfer of nucleoside followed by a low rate of phosphorylation, it should be possible to convert such a biphasic curve into a straight line when transport is selectively inhibited, so that transport (rather than internal phosphorylation) becomes rate-limiting. NBMI (6-nitrobenzyl mercaptinosine), a highly potent and specific inhibitor of nucleoside transport¹³, inhibits uptake

Fig. 2 *a*, Inhibition by NBMI of uridine uptake into quiescent 3T3 cells. Uridine uptake was measured as described for Fig. 1, except that the time of incubation was everywhere 6 min (at 37 °C). The cultures received NBMI at the concentration indicated on the abscissa for 10 min before the assay uptake. *b*, Effect of NBMI on the activity of uridine kinase isolated from 3T3 cells. The assay of uridine kinase was modified from that of Mizel and Wilson¹⁶. Cultures of quiescent 3T3 cells were washed with isotonic saline and scraped off the dish with a rubber policeman. The cells were pelleted, resuspended in 10 mM Tris-HCl, pH 7.5; 10 mM KCl; 2 mM MgCl₂, swollen for 10 min and disrupted in a Dounce homogeniser. The homogenate was centrifuged at 23,400g for 20 min. The incubation was performed at 37 °C in 400 μ l of solution containing 50 mM HEPES, pH 7.4; 2 mM ATP; 2 mM MgSO₄; 4 mM 3-PGA and 1 μ M 5-³H-uridine (5 Ci mmol⁻¹) and concentrations of NBMI indicated on the abscissa. The reaction was started by the addition of cell extract and stopped by boiling (3 min); samples of 100 μ l were removed at 3-min intervals from the incubation mixture. After centrifugation to remove denatured protein, 50- μ l samples were applied to DEAE filters (Whatman DE-81). The filters were washed and the radioactivity retained was measured as before¹⁶. The time course of the reaction was linear for at least 9 min of incubation. *c*, Uptake of labelled uridine as a function of time into 3T3 cells stimulated by serum (squares), or into non-stimulated cells (circles) or into non-stimulated cells treated for 30 min at 37 °C with 1.5 nM NBMI, uptake being measured in the presence of a similar concentration of NBMI (triangles). Uptake was measured as described for Fig. 1, except that the zero-time values were obtained in the presence of 50 nM NBMI, and the washing solution also contained this reduced concentration of NBMI. The zero-time values were: for the serum-stimulated cultures, 456 $\pm$ 23 (s.e.m., three determinations) c.p.m. per dish, for the non-stimulated cultures, 209 $\pm$ 50 (s.e.m., three determinations) c.p.m. per dish.

Fig. 3 Ion exchange chromatography of acid-soluble pools from quiescent cultures of 3T3 cells in different experimental conditions. Cultures of 3T3 cells were grown as described for Fig. 1 but in 90-mm diameter plastic dishes. The cultures were exposed for 30 min at 37 °C to DEM alone (*a*), DEM containing 0.5 nM NBMI (*b*) or DEM containing 10% foetal calf serum (*c*). At the end of the incubation the medium was removed rapidly, replaced by 3 ml of medium of the same composition in each case but containing 5-³H-uridine (28 Ci mmol⁻¹ 10 μ Ci ml⁻¹). After 6 s the radioactive medium was aspirated rapidly and the dishes were washed five times with 10 ml of ice-cold isotonic NaCl containing 100 nM NBMI. Then the cultures were extracted with 2 ml of 5% trichloroacetic acid for 1 h. The extracts from two cultures treated identically were combined and extracted five times with ether. (As control, we verified that 5-³H-uridine remains in the aqueous phase.) The aqueous phases were applied to columns (0.6 $\times$ 10 cm) of Bio-Rad AG1-x2 anion exchange resin (200-400 mesh) which had been converted to the formate form. Free uridine was eluted with 15 ml of H₂O; the phosphorylated nucleoside was subsequently eluted with 1 N HCl. The change to HCl is indicated by the arrows. Fractions of 1 ml were collected directly into scintillation vials; the samples 1 to 15 were adjusted to 1N HCl and then all the vials received 10 ml of Triton-toluene scintillation fluid. The radioactivity was determined in a Packard scintillation counter. To determine the amount of radioactive uridine that might remain in the extracellular space after washing, parallel cultures in DEM were exposed to 100 nM NBMI for 30 min, labelled for 3 s in the presence of the inhibitor to prevent the entry into the cells of any uridine and washed as described for the other cultures. In these conditions only a small amount of radioactivity was eluted in the tubes 5, 6, 7 and 8 (20, 66, 71 and 21 c.p.m. above background respectively) and thus, the radioactivity shown in the graphs represents only intracellular pools. The extensive washing procedure before extraction of the intracellular acid-soluble pools eliminates most of the extracellular uridine and the presence of NBMI during the washing prevents the efflux of free uridine¹⁴.

of uridine by intact 3T3 cells (Fig. 2a), but it does not alter nucleoside phosphorylation by cell-free homogenates prepared from parallel cultures (Fig. 2b). Thus, transport of nucleosides can be manipulated separately from their internal phosphorylation in 3T3 cells. When transport is made rate-limiting by addition of NBMI to quiescent cultures of 3T3 cells, the biphasic curve of uridine uptake is replaced by a straight line (Fig. 2c). When added to serum-stimulated cells, NBMI decreased the slope of the uptake curve (results not shown).

If phosphorylation is the rate-limiting step in the uptake of nucleosides by quiescent cells, more of the intracellular pool of uridine should be phosphorylated in serum-stimulated cultures than in the control ones, after a short exposure to labelled nucleoside. The phosphorylated nucleosides would be trapped inside the cell. We tested this possibility by measuring the radioactivity associated with the cells after labelling the cultures with ^3H -uridine for 5 s, rapidly replacing the radioactive medium with non-radioactive medium containing 1 mM uridine and incubating for another 10 s to allow for efflux of free ^3H -uridine. We found that 67.4% of the radioactivity remained associated with the cells in serum-treated cultures while 45.9% remained so associated in the non-stimulated cultures, a difference consistent with the prediction. To substantiate directly this conclusion, acid-soluble pools were labelled with high-specific activity ^3H -uridine for 6 s and were then analysed chromatographically. That intracellular phosphorylation rather than transport is rate-limiting in nucleoside uptake by non-stimulated cultures (Fig. 3a) is demonstrated by the fact that NBMI added at a low concentration (0.5 nM, which inhibits total uptake only by 25%) selectively reduces the labelling of the free-nucleoside pool by about 50% but does not modify the amount of radioactivity measured in the uridine-phosphate pool (Fig. 3b). If transport were rate-limiting, the inhibition of labelling by NBMI should be equal in both pools (free and phosphorylated uridine). Addition of serum to quiescent cultures changes considerably the composition of the acid-soluble pools (Fig. 3c); serum increases the radioactivity recovered in the nucleoside phosphate pool and considerably reduces that corresponding to the pool of cellular free uridine (Fig. 3c). Clearly, serum stimulates the rate of conversion of ^3H -uridine to phosphorylated nucleosides. Similar results were obtained in four independent experiments. The percentages of radioactivity found in the phosphorylated pools were $48 \pm 5\%$ and $88 \pm 4\%$ in the control and serum-activated cultures respectively, which are consistent with the washout experiments described here.

Taken together, our experiments support the notion that the stimulation of uridine uptake by serum in density-inhibited 3T3 cells results from an increase in the rate of internal phosphorylation rather than that of transport. How external growth-promoting factors regulate this rapid internal process warrants further investigation.

We thank Dr P. Plagemann for sending a copy of his manuscript before publication, Dr Z. I. Cabantchik for NBMI, Margaret Grimaldi and Ann Duffy for preparation of cell cultures and Drs J. Schneider and L. Heppel for helpful comments. W.D.S. thanks the NCI for financial support.

Activation of melanoma tyrosinase by a cyclic AMP-dependent protein kinase in a cell-free system

REGULATION of pigmentation is of considerable importance throughout the animal kingdom. Photoprotection, social behaviour, and a number of disorders like albinism, vitiligo, and melanoma are affected by the amount and distribution of melanin in the organism. Melanin is synthesised in melanosomes beginning with the oxidation of tyrosine to dihydroxy-phenylalanine (DOPA) by the enzyme tyrosinase. In Cloudman S91 melanoma cells, tyrosinase activity and melanisation are stimulated by elevated intracellular levels of cyclic AMP¹, apparently through the inactivation of an inhibitor of tyrosinase². We initiated a series of experiments to identify the molecules controlling tyrosinase activity. Kuo and Greengard's observations on the widespread occurrence of cyclic AMP-dependent protein kinases throughout the phyla suggested that protein phosphorylation reactions might be involved³. We describe here a cell-free system in which tyrosinase is activated following the addition of a cyclic AMP-dependent protein kinase isolated from melanoma cells. The kinetics of the reaction in the cell-free system are similar to those in intact cells. The activation of tyrosinase is completely dependent on the protein kinase and is enhanced by cyclic AMP, ATP, and magnesium. The activation involves the removal of an inhibitor of tyrosinase; in addition, a phosphoprotein phosphatase is present which is distinct from the inhibitor but which appears to antagonize the kinase-mediated reaction.

A cell line designated PS1-HGPRT-1 (ref. 4) was chosen for these studies because of its low basal tyrosinase activity which increases 5-50-fold about 15 h after the addition of melanocyte stimulating hormone (MSH) or dibutyl cyclic

Table 1 Lack of effect of kinase on tyrosinase activity in extracts of cells exposed to MSH before collection

Time of incubation (h)	Additions to reaction	Tyrosinase activity (^3HOH production c.p.m.)
0	None	9,670
	Kinase	9,242
24	None	10,800
	Kinase	7,930

Cells were cultured for 5 d with MSH (2×10^{-7} M) present in the medium. They were collected and an S30 fraction was prepared as described in the legend to Fig. 1. Each reaction tube contained S30 (0.14 mg ml^{-1}), cyclic AMP (10^{-6} M), ATP (2×10^{-4} M), and magnesium acetate (1×10^{-3} M) in Tris-HCl (50 mM, pH 6.2). Protein kinase, when added, was at a concentration of 0.16 mg ml^{-1} . Reactions were incubated at 30°C , and at the times indicated 20 μl -samples were withdrawn and assayed for tyrosinase activity as in Fig. 1.

Fig. 1 Activation of tyrosinase in a cell-free system. Cells were cultured in monolayer as described previously⁶. Log-phase cultures were fed fresh medium within 24 h of collection. They were collected with 5 mM EDTA in Ca-Mg free Tyrodes salt solution at room temperature, collected by centrifugation (2,500g for 5 min), and washed three times in NaCl (156 mM, room temperature) by successive centrifugations. The washed pellets of cells were resuspended in 10 volumes of ice cold Tris-HCl (25 mM, pH 7.4) containing 0.5% Triton X-100, and lysed by mixing gently with a Vortex Genie mixer every 2-3 min. over a 20-min period. The lysed cells were centrifuged (30,000g, 15 min, 4 °C), the pellets were discarded, and the supernatant solution (S30) was dialysed against 2,000 volumes of Tris-HCl (25 mM, pH 7.4) for 5 h at 4 °C. The dialysed S30 fraction was then stored at -90 °C in convenient aliquots where it remained stable for at least 6 months. The S30 fraction contained 0.8 mg ml⁻¹ protein as determined by the method of Lowry *et al.*⁷. Cyclic AMP-dependent protein kinase (also referred to as kinase) was partially purified from tumours originating from the same cell line inoculated into DBA 2J mice. Tumours were removed from mice, rinsed with NaCl (156 mM), and homogenised in 3 volumes ice-cold KPO₄ (5 mM, pH 6.8). All further steps were at 4 °C. The homogenate was centrifuged first at 3,000g for 5 min to remove large particulate matter, and then at 30,000g for 15 min. An equal volume of hydroxyapatite (0.5 gml⁻¹ in 5 mM NaPO₄, pH 6.2) was added to the 30,000g supernatant fraction, the mixture was stirred (5 h), and then centrifuged (30,000g, 15 min). More than 90% of the cyclic AMP-dependent protein kinase activity was associated with the hydroxyapatite while all tyrosinase activity remained in the supernatant fraction. Kinase was eluted by suspending the hydroxyapatite in three volumes KPO₄ (0.3M, pH 6.8, containing mercaptoethanol, 4 mM, and glycerol, 10%), stirring (15 h, 4 °C), and then centrifuging (30,000g, 15 min 4 °C). The supernatant fraction contained the kinase activity and was dialysed against 1,000 volumes buffer A (KPO₄, 10 mM, pH 6.8, mercaptoethanol, 2 mM, glycerol, 10%) overnight at 4 °C and then placed on a DEAE-cellulose column equilibrated with the same buffer. Kinase was eluted from the column with a salt gradient from buffer A alone to buffer A containing KPO₄ (0.3 M, pH 6.8). Two prominent peaks of kinase were eluted from the column, peak I containing more than 80% of the kinase activity and peak II containing the remainder. This kinase elution profile was essentially the same as that seen in other tissues by several groups (for example, see ref. 8). Fractions containing peak I kinase were pooled and made 60% with (NH₄)₂SO₄. The kinase precipitated in these conditions and was stored in aliquots at 4 °C where it remained stable for at least 8 months. Although this procedure resulted in a substantial purification of the kinase, the preparation contained 10-15 protein bands when analysed by SDS-acrylamide gel electrophoresis. The preparation was free of tyrosinase activity, tyrosinase inhibitors, and protein phosphatase. The cell system contained the following components: S30 fraction (0.16 mg ml⁻¹). Tris-HCl (50 mM, pH 6.2), gentomycin (0.05 mg ml⁻¹), and where noted kinase (0.14 mg ml⁻¹), cyclic AMP (10⁻⁶ M), ATP (2 × 10⁻⁴ M), and magnesium acetate (10⁻² M). At times indicated samples were withdrawn and assayed for tyrosinase activity. The tyrosinase assay was a modification of the method of Pomerantz⁹. Samples (20 µl) were mixed with 10 µl of a solution containing ³H-tyrosine (50 µCi ml⁻¹, 1.5 × 10⁻⁴ M), dihydroxyphenylalanine (dopa, 2.5 × 10⁻⁴ M) and NaPO₄ (5 × 10⁻² M, pH 6.8). The mixture was incubated at 37 °C for 20 min, and 1 ml of activated charcoal (100 mg ml⁻¹ in citric acid, 0.1 M) was added. This mixture was then mixed briefly with a Vortex Genie mixer, centrifuged (2,000g, 5 min) and the supernatant fraction containing ³HOH was poured over a Dowex 50 column (1 cm in a Pasteur pipette) equilibrated with 0.1 M citric acid. The column eluate was counted in a liquid scintillation counter. Tyrosinase activity was linear over the 20 min incubation at 37 °C and was enhanced about fivefold by the addition of dopa. Control (●), added cyclic AMP, ATP, Mg²⁺ (○), added kinase (×), added kinase and cyclic AMP, ATP, Mg²⁺ (□). These experiments were repeated more than 10 times with similar results each time.

AMP (Bt.cAMP) to the culture medium. A 30,000g supernatant (S30) fraction of these cells was prepared and incubated with or without the additions of cyclic AMP-dependent protein kinase, cyclic AMP, ATP, and magnesium. Tyrosinase activity increased dramatically after a lag period of several hours (Fig. 1). The increase was enhanced by cyclic AMP, ATP, and magnesium, all of which were necessary for maximum response. The optimal pH for the reaction was 6.2 and the optimal temperature was 30 °C. The kinetics of activation were similar to those observed in intact cells exposed to Bt.cAMP (Fig. 2). Cyclic AMP-dependent protein kinase activity was present in the S30 fraction, and if the concentration of the S30 was increased in the reaction mix, the activation reaction was no longer dependent on exogenously added kinase (data not shown). We first noticed the activation of tyrosinase when we inadvertently left a concentrated S30 fraction at room temperature and found the next day that the tyrosinase activity had increased by more than 100-fold.

When an S30 fraction was prepared from cells that had been exposed in culture to MSH for 5 d before collecting, the tyrosine activity was high in fresh extracts and no activation occurred following the addition of protein kinase (Table 1). In these experiments the addition of kinase actually caused a slight decrease in tyrosinase activity.

To gain additional evidence for the role of protein kinase in the activation of tyrosinase we investigated the effects

Table 2 Effects of kinase modulator on protein kinase and the activation of tyrosinase

Experiment	Additions	Protein kinase activity (ATP ³² incorporation, c.p.m.)	Tyrosinase activity (³ HOH production, c.p.m.)
a	Kinase only	1,100	—
b	Kinase + modulator	320	—
c	Cell-free system	—	7,400
d	Cell-free system + modulator added at zero time	—	750
e	Cell-free system + modulator added at 24 h	—	7,650

Protein kinase modulator was prepared from calf brain through step 2 of the procedure of Donnelly *et al.*⁹. Experiments a and b were measurements of cyclic AMP-dependent protein kinase activity. Each reaction mix contained NaPO₄ (50 mM, pH 6.8), kinase (0.14 mg ml⁻¹), ATP³² (10⁻⁴ M, 0.2 Ci mM⁻¹), cyclic AMP (10⁻⁶ M), magnesium acetate (10⁻² M), and histones as substrate (Sigma, calf thymus type 11A, 200 µg ml⁻¹). Mixes (100 µl) were incubated for 5 min at 30 °C and the reactions were stopped by the addition of ice cold trichloroacetic acid (TCA 10%). Precipitates were washed several times in TCA and counted in a liquid scintillation counter. Experiments c-e were measurements of tyrosinase activity after 24 h in the cell-free system described in Fig. 1. Each reaction contained S30 fraction, kinase, cyclic AMP, ATP, and Mg²⁺. Modulator was added at a concentration of 0.34 mg ml⁻¹.

Fig. 2 Activation of tyrosinase in cultured melanoma cells by Bt₂cAMP. Cells (10⁶) were cultured in F10 medium (4 ml) containing 3,5-³H-tyrosine (New England Nuclear, 1 μ Ci ml⁻¹, final specific activity 88 Ci mol⁻¹) and at the times indicated 0.5-ml aliquots of medium were withdrawn and mixed with 1 ml charcoal as described in Fig. 1 to measure ³HOH. Counts represent the amount of ³HOH formed during each time period. This experiment was carried out in parallel to that presented in Fig. 1. Bt₂cAMP (10⁻³ M) (open bar); control (cross hatched bar).

of an inhibitor of cyclic AMP-dependent protein kinases (protein kinase modulator)⁹. Kinase modulator inhibited both the protein kinase and the activation of tyrosinase but had no effect on activated tyrosinase (Table 2).

The kinase-mediated activation of tyrosinase involved the removal of an inhibitor of tyrosinase. Freshly-thawed S30 fractions contained tyrosinase inhibitory activity which disappeared after the activation of tyrosinase. The inhibitor

Fig. 3 Decay of phosphatase activity at 30 °C. An S30 fraction was incubated at 30 °C and at the times indicated aliquots (20 μ l) were withdrawn, mixed with ³²P-labelled proteins described in the legend to Table 4, and phosphatase activity was measured.

Table 3 Evidence for tyrosinase inhibitory activity in cell extracts*

Additions	Tyrosinase activity (c.p.m. ³ HOH production)
Buffer only (controls)	22,422
a, freshly-thawed S30 fraction	7,500
b, S30 fraction incubated 55 °C, 30 min	6,400
c, S30 fraction incubated 30 °C, 24 h	1,400

*A cell-free system containing S30 fraction, kinase, cyclic AMP, ATP, and Mg²⁺ was incubated 24 h at 30 °C as described in Fig. 1. At this time aliquots (10 μ l) were withdrawn and mixed with buffer only in controls or additional S30 fraction (10 μ l, 0.04 mg) which had been either a, freshly thawed; b, incubated at 55 °C for 30 min, or c, incubated at 30 °C for 24 h. ³H-tyrosine and dopa were added as in Fig. 1, the mixtures were incubated for 20 min at 37 °C and the amount of ³HOH produced measured.

activity was stable to heating at 55 °C for 30 min, or 30 °C for 24 h (Table 3).

Phosphoprotein phosphatase (referred to as phosphatase) activity was present in freshly-thawed S30 preparations (Table 4). The disappearance of acid precipitable ³²P counts was not due to proteolytic digestion of the ³²P-labelled phosphoproteins since ³H-leucine-labelled proteins mixed into the assay tubes were not degraded during the same time period. Phosphatase activity in the S30 fractions was destroyed by heating the fractions at 55 °C for 30 min. (Table 4) and had a half life of 11 h at 30 °C (Fig. 3). The kinase-mediated activation of tyrosinase took place after the phosphatase had decayed substantially (cf Fig. 1). This finding raised the possibility that the lag period in the activation of tyrosinase was due to an antagonism between kinase-mediated phosphorylations and phosphatase-mediated dephosphorylations. Evidence supporting this possibility comes from the finding that alkaline phosphatase inhibited the activation reaction (Table 5). Since the phosphatase activity was heat-sensitive and tyrosinase inhibitory activity was not (Table 3), it is clear that the two are distinct from one another.

Data from several experiments show that the control of melanisation in Cloudman S91 melanoma cells is complex (see ref. 1 for a review). MSH causes an increase in intracellular levels of cyclic AMP by binding to cell surface receptors in the G2 phase of the cell cycle and activating adenylate cyclase¹⁰. Results from the cell-free system described here indicate that elevated levels of cyclic AMP activate a protein kinase which in turn causes an activation

Table 4 Phosphoprotein phosphatase activity in cell extracts

Time of Incubation (min)	Acid precipitable ³² P-proteins (c.p.m.)	Acid precipitable ³ H-proteins (c.p.m.)
0	465	11,500
60	219	12,200
60, with heated S30	455	11,200

Substrate for the phosphoprotein phosphatase assay was prepared as follows: Freshly-thawed S30 was heated (55 °C, 30 min) to destroy endogenous phosphatase activity. A mixture was then prepared containing the heated S30 (0.16 mg ml⁻¹) protein kinase (0.14 mg ml⁻¹), ATP³² (10⁻⁵ M), magnesium acetate (10 mM), NaPO₄ (50 mM, pH 6.8) in a total volume of 5 ml. The mixture was incubated at 30 °C for 5 min, chilled on ice, and the ³²P-labelled proteins were separated from low molecular weight components on a Sephadex G25 column equilibrated with Tris-HCl (0.1 M, pH 7.4). Phosphatase activity was measured by adding the ³²P-labelled proteins to freshly thawed S30, incubating at 37 °C, and following the disappearance of acid precipitable ³²P counts on filter disks with time. To distinguish phosphatase activity from protease activity, ³H-leucine-labelled proteins isolated from cells cultured in ³H-leucine were mixed into the reaction tubes.

of tyrosinase. These findings suggest a simple model in which the kinase catalyses the phosphorylation of a tyrosinase inhibitor and thus inactivates that inhibitor. Proof for such a model can come only when the individual components of the system have been purified. Data were presented previously indicating that intact cells contain a tyrosinase inhibitor which is inactivated on exposure of the cells to MSH (ref. 2).

The following observations lead us to conclude that the events we have observed in the cell-free system are the same as those which occur in cultured cells. (1) Tyrosinase inhibitory activity is removed in both cases. (2) Extracts from cells pretreated with MSH have high tyrosinase activity and cannot be activated further in a cell-free system. And (3), the kinetics of activation are similar. It

Table 5 Effects of alkaline phosphatase on the activation of tyrosinase

	Tyrosinase activity (c.p.m. ^3HOH production)
Cell-free system	12,700
Cell-free system + alkaline phosphatase	3,500

A cell-free system containing S30 fraction, kinase, cyclic AMP, ATP, and Mg^{2+} was incubated for 24 h in the presence or absence of alkaline phosphatase (Boehringer Mannheim, calf intestine, 0.05 mg ml $^{-1}$).

should be noted that this report describes only the activation of tyrosinase, that is, the enzyme which catalyses the conversion of tyrosine to dopa. In none of the experiments did we see an increase in melanin formation, a result which we do not understand. In the melanin biosynthetic pathway, tyrosinase catalyses the oxidation of tyrosine to dopa and then of dopa to dopa quinone. Since the results reported here deal only with the first step in the reaction, it is possible that the second step is under separate controls and was not activated in our experiments. Using the cell-free system, we hope eventually to demonstrate increased melanisation and to identify the molecules controlling tyrosinase activity.

Properties of an identified histamine-containing neurone

THE cellular role of neuronal histamine is still not understood, although a transmitter function is suspected¹. Advances have been restricted largely because of the lack of experimentally amenable, peripheral, histamine-containing systems in the vertebrates. As an alternative approach to the problem, we have sought an identifiable histamine-containing neurone in the central ganglia of a molluscan species. Previous studies on repeatedly identifiable neurones of this group have facilitated study of individual neurones known to contain, for instance, dopamine or 5-hydroxytryptamine, and the synaptic connections made by these neurones². Here we briefly describe the localisation of one particular histamine-containing neurone, its content of histamine, ability to take up histamine from an incubation medium, the type of granulated vesicles it contains and the influence of certain transmitter substances on its electrical activity.

Experiments were made on the pond snail, *Lymnaea stagnalis*. Neurones were initially screened using light microscope autoradiography after exposure to tritiated histamine, on the assumption that those neurones which contain histamine would also preferentially take up the amine from the extracellular fluid. The central ganglia were incubated at 18–20 °C in 100 μl of physiological solution³ containing 25 μM 2,5- ^3H -histamine dihydrochloride (1 Ci mmol $^{-1}$, Radiochemical Centre, Amersham) for 2 h. After washing in a continuous saline flow for 30 min, the tissues were fixed in 1% glutaraldehyde in 0.067 M phosphate buffer (pH 7.4), dehydrated through ethanol series and embedded in paraffin wax. Serial sections 7 μm thick, were coated with Kodak AR 10 stripping film, exposed for 10–14 d in the dark and developed in Kodak D 19. A specific population of neurones was found to be repeatedly labelled after this treatment. All of these neurones were small (<50 μm diameter) and not readily identifiable in intact preparations, with the exception of a single large neurone (Fig. 1) situated on the anterior dorsal surface of the visceral ganglion. The perikaryon of this neurone is 90–170 μm across its major axis and can be readily located in the majority of preparations by virtue of its size and position.

Histamine was assayed in extracts of individually dissected perikarya using a radioenzymatic method⁴. The

Fig. 1 Autoradiogram of a section of the visceral and left parietal ganglia of *Lymnaea* after incubation in physiological solution containing ^3H -histamine. Dense aggregations of silver grains are seen over the perikaryon of the giant visceral neurone (large arrow), and over portions of one of its main axon branches (small arrows) in the neighbouring left parietal ganglion. Scale bar represents 300 μm .

Table 1 Intracellular histamine concentration

Neurone	Intracellular histamine concentration $\pm$ s.e.m. (μ M)
Giant visceral neurone (<i>Lymnaea</i>)	275 ± 11.7 ($n = 4$)
Dopamine-containing neurone (<i>Planorbis</i>)	38.7 ± 3.8 ($n = 3$)
Non-aminergic neurone (<i>Lymnaea</i>)	None detectable ($n = 3$)

large neurone described above which took up histamine was found to contain a high level of histamine, whereas other identified neurones, a non-amine-containing neurone of *Lymnaea* (this neurone, located in a similar position to the VD1 of Winlow and Benjamin⁵, reacted negatively when the ganglia were examined by formaldehyde histo-fluorescence for primary amines) and the giant dopamine neurone of *Planorbis*⁶, contained much less histamine (Table 1). High specific histidine decarboxylase activity is associated with the part of the visceral ganglion containing the perikaryon of the histamine-rich neurone and recent experiments show that there is an enzyme within the perikaryon capable of synthesising histamine from histidine (J.D.T., unpublished).

For electron microscopy, individual neurones were dissected free from glutaraldehyde-fixed ganglia, post-fixed in 1% osmium tetroxide in 0.2 M veronal buffer (pH 7.4), stained in 1% uranyl acetate, dehydrated through acetone series and embedded in Epon. Examination of thin sections of the identified histamine-neurone by electron microscopy (Philips EM 301) revealed large aggregations of membrane bound dense-cored vesicles, of 80–200 nm diameter (Fig. 2), and extensive and highly organised rough endoplasmic reticulum in the cell cytoplasm, as well as numerous elongated mitochondria and lysosome-like bodies. The dense cores are larger than those of vesicles reported in the perikarya of molluscan dopamine-containing⁶ and 5-hydroxytryptamine-containing⁷ neurones. The vesicles also seem to occur in much larger aggregations than in these other amine-containing neurones.

The histamine neurone was readily located in the isolated ganglionic preparation for intracellular electrical

recordings using conventional techniques. Small excitatory postsynaptic potentials and inhibitory postsynaptic potentials were recorded from the neurone in different preparations, without applying any stimulation. Occasionally the excitatory input was sufficient to cause the cell to fire action potentials. The effects of some transmitter substances were tested on the activity of the neurone. These compounds were applied iontophoretically from fine-tipped micropipettes placed close to the perikaryon, using current pulses of 50–300 nA for durations of 0.5–2.5 s. Acetylcholine caused a biphasic depolarising–hyperpolarising response. The first phase of the response was comparatively fast and blocked with 10^{-4} M hexamethonium bromide. The second phase was not blocked with this concentration of hexamethonium; it was very rapidly desensitised and chloride dependent. 5-Hydroxytryptamine also produced a rapidly desensitising, chloride-dependent hyperpolarising response. In contrast, iontophoretically applied histamine, dopamine, glutamate and γ -aminobutyric acid were without any obvious effects. But addition of histamine acid phosphate directly to the perfusion fluid resulted in a gradual depolarisation of the neurone, due to an increase in membrane conductance, and spike firing.

The giant visceral neurone has numerous axon branches with ramifications in other ganglia. Some branches leave the central ganglia for the periphery (J.D.T., S. Logan and G.A.C., unpublished data). As yet, however, the functional role of the neurone is not known.

In summary, there is a giant histamine-containing neurone in the visceral ganglion of *Lymnaea stagnalis*. The histamine concentration in this neurone (275 μ M) is comparable with that recently reported for the C2 neurones (300–400 μ M) located in the cerebral ganglia of *Aplysia californica*⁸. The *Lymnaea* histamine-neurone contains large aggregations of granulated vesicles of distinctive appearance and it is capable of taking up histamine from the surrounding medium. The neurone can be readily located for electrophysiological experiments and would seem to provide a suitable model system for analysing the cellular role of neuronal histamine.

We thank Professor J. C. Schwartz for assistance in histamine and histidine decarboxylase estimation. This work was supported by EMBO. J.D.T. was a Wellcome Research Scholar during the major part of this project.

5-Hydroxytryptamine receptors on visceral primary afferent neurones in the nodose ganglion of the rabbit

5-HYDROXYTRYPTAMINE (5-HT) is known to be a powerful activator of the sensory nerve endings¹ and a potent stimulant of sympathetic ganglia^{2–4}. Very little is known, however, about the nature of 5-HT receptors and the ionic basis of the 5-HT-induced membrane potential changes^{5,6}.

Here I report the existence of 5-HT receptors on the soma of afferent neurones of the nodose ganglion of the vagus and the ionic requirements of the response elicited by activation of these receptors.

The nodose ganglion was excised from the rabbits anaesthetised with pentobarbitone (30 mg per kg body weight intravenously) and intracellular recordings were made from the somata of neurones by methods essentially similar to that of Jaffe and Sampson⁷. 5-HT was applied either by superfusion as an addition to Krebs solution or by iontophoresis. Electrodes used for iontophoresis were filled with 0.1 M 5-HT adjusted⁸ to pH 3.8–4.0 and had tip resistances of 100–200 M Ω .

A majority of neurones (76 out of 88) were depolarised by 5-HT. Figure 1a shows a typical response to superfusion with a solution containing 5×10^{-6} M 5-HT. In most instances, the onset of the depolarisation was rapid and concentration dependent. The minimal effective concentration to produce the depolarisation was 10^{-7} M, and the maximal response was obtained at concentrations greater than 10^{-4} M. Repetitive firing frequently occurred during the rising phase of the depolarisation. The depolarisation was followed by an almost equally rapid repolarisation, then a hyperpolarisation (after-hyperpolarisation) of approximately 5 mV. The after-hyperpolarisation was in turn followed by a long-lasting depolarisation of a few millivolts.

Iontophoretic application of 5-HT elicited a response similar to that induced by superfusion. As seen in Fig. 1b, a 10^{-8} -A pulse (80 ms) sufficed to produce a depolarising response and a typical biphasic response was induced with a 10^{-7} -A pulse.

All the components of a 5-HT response were associated with a reduction of membrane resistance as by the decrease in the amplitude of the electrotonic potentials superimposed on the response (Fig. 1a).

In an attempt to determine the ionic species involved, the 5-HT responses were studied in various ionic media and at different membrane potentials. Replacement of external sodium by choline or Tris (hydroxymethyl)aminomethane abolished not only the rapid and residual depolarisations but also the after-hyperpolarisation. Removal of external potassium caused a slight decrease of the rapid depolarisation, a marked enhancement of the after-hyperpolarisation and no significant alteration in the residual depolarisation. Replacement of external chloride by acetate reduced the resting potential by approximately 15 mV and nearly halved the amplitude of 5-HT response. This reduction in amplitude was, however, eliminated when the membrane potential was restored by passing hyperpolarising current through the microelectrode.

When the membrane was depolarised stepwise, the rapid depolarising response was reduced accordingly and finally reversed at a certain level (-0.1 ± 2.0 mV s.e., $n=8$). This reversal level was at least 30 mV below the sodium equilibrium potential determined from the peak of the action potential. The after-hyperpolarisation could be reversed at -87 ± 2.5 mV ($n=8$) at which voltage the after-hyperpolarisation of the action potential also inverted. The reversal levels of the rapid depolarisation and the after-hyperpolarisation were unaltered by the replacement of external chloride with acetate.

These findings suggest that during the rapid initial depolarising response to 5-HT, there is a simultaneous increase in sodium and potassium conductance and during the after-hyperpolarisation only potassium conductance is increased. Since, however, both the initial depolarising and hyperpolarising responses are abolished in sodium-free media, the possibility arises that the after-hyperpolarisation is triggered by the entry of sodium ions. The fact that the residual depolarisation was abolished by deprivation of sodium but unaltered by withdrawal of potassium indicates

Fig. 1 5-HT-induced responses in afferent neurones of the rabbit nodose ganglion. Intracellular records from three different neurones show; *a*, depolarising response to 5×10^{-6} M 5-HT applied by superfusion for 20 s (between two arrows). Electrotonic potentials were elicited by square pulses (0.3 nA, 100 ms) every 2 s. *b*, Depolarising responses to 5-HT iontophoresed by current pulses (80 ms) of 20 nA (left), 35 nA (middle) and 85 nA (right). *c*, Hyperpolarising response to 5-HT iontophoresed by a current pulse of 80 nA and 100 ms. Electrotonic potentials were elicited by square pulses (0.25 nA, 50 ms) every 0.3 s. In each record the upper trace shows electrotonic (*a* and *c*) or iontophoretic (*b*) current pulses and the lower trace the membrane potential changes. Resting potentials of the three neurones were -58 mV (*a*), -62 mV (*b*) and -55 mV (*c*). Action potentials that appeared on the rising phase of 5-HT-induced depolarisation were attenuated by the ink-writing recorder.

that the residual component is associated with a small but sustained sodium permeability.

In a small number of neurones (5 of 88), 5-HT evoked a simple hyperpolarising response with no preceding or succeeding depolarisation as shown in Fig. 1c. The response varied in amplitude from 3.8 to 11.2 mV and in duration from 5.4 to 10.4 s and was consistently accompanied by a reduction of membrane resistance (Fig. 1c). Removal of potassium enhanced the hyperpolarisation, and displacement of membrane potential beyond -90 mV reversed its polarity. These characteristics reflect that an increased potassium conductance is the major, if not the exclusive, cause of this hyperpolarising response.

A similar group of neurones (7 of 88) did not show any response to 5-HT applied by iontophoresis and by superfusion.

Thus the majority of vagal afferent neurones are endowed with 5-HT receptors which are most commonly depolarising and only rarely hyperpolarising. The functional role of these receptors is obscure at the present. Presumably they could be a remnant of an embryonic stage in which 5-HT receptors migrate from the cell soma to the axon terminals. A number of authors have suggested that the depolarising response of the same population of neurones to GABA is similarly mediated by residual receptors (ref. 9). Much in the same way the 5-HT receptors would offer an opportunity to investigate their physiological and pharmacological characteristics in conditions which cannot as yet be achieved at the axon terminal.

This study was supported by the Ministry of Education, Science and Culture of Japan.

A regenerating neurone in the leech can form an electrical synapse on its severed axon segment

WHEN the nervous system develops, its constituent neurones establish connections with certain selected elements while rejecting others in a fashion that gives the completed system the precision it requires to function. Such specificity is also manifested during regeneration in the central nervous system (CNS)¹⁻³. For example, regeneration and recognition have been demonstrated with electrophysiological techniques in the leech CNS^{4,5}, where individual sensory neurones can select their normal postsynaptic targets from among apparently hundreds of alternatives, re-establishing chemical synaptic connections. The leech CNS has also provided an example of neurones re-establishing electrical continuity after surgical disruption of a connecting axon⁶. Such electrically connected 'S-cell' interneurons, one of which is situated in each of the 21 segmental ganglia of the leech, are linked at the ends of their axons by electrical synapses across which large molecules cannot pass⁷. The synapse between two S interneurons occurs in the axon bundles (connectives) that join ganglia. The discovery of this junction and the use of the enzyme horseradish peroxidase (HRP) as an intracellular marker have permitted a detailed morphological and physiological analysis of the steps by which a regenerating axon re-establishes synaptic contact with its proper target. We report here that one such step can be the formation of an electrical synapse between the regenerating neurone and its own severed axon segment, thereby restoring the neurone's functional integrity.

Except at the extreme ends of the ventral nerve cord, the axons of S cells meet at about the midpoint along the connectives between the ganglia (Fig. 1c). This single region of contact between neighbouring S cells is the site of the electrical synapse, across which nerve impulses can pass in either direction as they traverse the entire length of the intact nerve cord. In the present experiments the cord was crushed close to one ganglion (either 8, 9, 10 or 11) so that the electrical synapse between S cells was not directly affected by the lesion. This procedure severs all axons including those in the bundle of nearly a hundred in which the S-cell axon travels. Animals were allowed to recover in spring water at 16 °C, the usual holding temperature. Distal to the crush the operation leaves an isolated axon segment about 1 or 2 mm long that remains viable and linked through an electrical synapse to the adjacent S cell, termed here the 'target' cell of the regenerating process.

The extent of regeneration was determined by removing a short chain of ganglia including the lesion from the animal, and then recording from the chain in the leech Ringer's solution^{8,9}. Electrical coupling between cells was detected with intracellular microelectrodes inserted into S-cell somata and with suction electrodes applied to the connectives. Intracellular microelectrodes were filled either with 4 M potassium acetate or with a solution of 2% horseradish peroxidase in 0.2 M potassium chloride. To mark the entire arborisation of an S cell, peroxidase solution was injected under pressure into the S-cell soma through the recording microelectrode, the chain of ganglia incubated for 6-12 h in a modified L-15 culture medium¹⁰⁻¹¹, and the histochemical reaction and subsequent treatment for light or electron microscopic observation performed as previously

described¹²⁻¹³. The diaminobenzidine reaction product is not seen in uninjected cells that are electrically coupled to the injected neurone, but owing to the activity of endogenous peroxidases some reaction product can appear in peroxisomes in all cell somata, especially in culture medium.

In six experiments the restoration of electrical coupling and subsequent conduction of impulses between S cells occurred in less than 4 weeks. In these preparations there was no anatomical contact between neighbouring S cells, as determined with the HRP marking technique. Rather, when HRP was injected into both the regenerating injured S cell and its target S cell (which showed no sign of growth) the reaction product revealed a gap as large as a millimeter between the stained axons (Fig. 1a). This distance decreased during the month following the lesion. In these instances

Fig. 1 The regenerating axonal processes of the S cell surround the neurone's severed distal segment. *a*, The axon proximal to the crush (below) branches as it crosses the crush in the centre of the connective and remains branched as it forms a basket of processes along the site of the distal segment. The marked cell ends abruptly several hundred micrometres before reaching the next S cell (not shown) whose extent had also been determined with peroxidase injections. The growing tip is shown in *b*. In this plane of focus the marked processes are seen to surround portions (indicated at three locations by arrows) of the distal segment (18 d). *c*, Schematic diagrams from peroxidase-injected preparations indicating the normal and experimentally induced connection (anterior at top). *d*, Electron micrograph of connective cross section showing two stained processes of the regenerating neurone (R_1 and R_2) near the distal segment (S), identified by its large size, dorsal position in Faivre's nerve and light cytoplasm. Inset: where the regenerating axon (R_1) apposes the segment are points at which the membranes are separated by no more than 4-5 nm (arrowheads), the presumed gap junctions (34 d).

Fig. 2 *a*, The distal axon segment (here of S cell in ganglion 11) remains functionally connected to the adjacent target S cell (in ganglion 10) after crushing close to ganglion 11 (19 d previously). Suction electrodes record anteriorly (*a*) and posteriorly (*p*) to ganglion 10, in which the target S cell (S_{10}) has been penetrated with a recording microelectrode. Prior recording and stimulation posterior to the crush (=) demonstrated that the S-cell connection from ganglion 11 had not regenerated. The recordings here illustrate respectively that (*stim. p*) threshold stimulation at *p* excites S_{10} whose impulse is also recorded at *a*; (*stim. S₁₀*) direct activation of S_{10} with a depolarising pulse of current through the recording microelectrode activates not only its own axon recorded at (*a*), but also the axon of the distal stump recorded at *p*; and (*stim. a*) anterior connective stimulation at threshold directly activates S_{10} and subsequently the distal stump at *p*. In the diagram on the left, the thickened line in the connectives represents the peroxidase-stained axon of S_{10} , which terminated more than one millimetre from point *p*. At this distance the suction electrode (*p*) would not have directly activated or recorded from S_{10} . *b*, Coupling of S-cells through the distal segment. The connective between ganglia 8 and 9 was crushed 20 d previously. S cells (S_8 and S_9) that, on subsequent marking with peroxidase, were found not to have regenerated a direct contact nevertheless show normal functioning. Upper: impulses generated in S_8 with the recording microelectrode are propagated to S_9 and vice versa. Lower: hyperpolarising currents injected into S_8 or S_9 spread into the adjacent S cell, indicating good coupling through the uninjected process.

of coupled neighbours not in direct contact, the regenerating neurone formed a basket of processes around a 5–8- μ m cylinder that in the electron microscope is identified as its own distal segment (Fig. 1*b, c* and *d*). Glial processes are seen between most of the regenerating and old axons, but at the sites of contact between the regenerating process and the distal segment are occasional points of close apposition. Tilting of the specimen in the electron microscope reveals that the membranes are separated by no more than 4–5 nm. These areas of contact, though small, resemble gap junctions between neighbouring S cells in the normal connective⁷ and those found in other invertebrates¹⁴. Electron microscopic examination of cross sections through the connective in the region of the discontinuity between injected S cells confirms that S-cell regeneration is not complete and that the distal axon segment is linking the S cells.

During the month after the lesion is made the distal axonal segment can retain its integrity and remain functionally connected to the target S cell through the old electrical junction. The S-cell axon normally has a low threshold and generates the largest impulses recorded from the connective. These physiological properties and nearly normal ultrastructure are retained by the distal axon segment during the first month. Figure 2*a* shows that before the two S cells have become functionally reconnected the isolated distal segment can still excite and be excited by the adjacent target S cell.

In two or three weeks the coupling between adjacent S cells through the isolated axonal link develops a nearly normal⁶ strength with impulses conducted in both directions (Fig. 2*b*). This coincides with an increasingly extensive association between the regenerating neurone and its distal segment, which itself remains connected to the target S cell.

When coupled neurones are examined at progressively later times, the distance shortens between the axon tips of the injected adjacent S cells. For example, the cell in Fig. 1*d* had grown 700 μ m to within 150 μ m of the target S cell. After about 1 month no separation between coupled cells is seen. This suggests that neurones already functionally connected through the distal segment can eventually re-establish direct contact at the normal site of synapse through continued regeneration of the lesioned neurone. Growth beyond the normal synaptic contact has not been observed even after six months.

Regenerating S cells establish strong electrical synapses specifically with S cells. In several experiments electrical coupling was not detected between the regenerating S cell in one ganglion and cells near the S cell in adjacent ganglia. Moreover, an impulse in the regenerating S cell will evoke only an S-cell impulse recorded in the connectives. Certainly the close anatomical association between the regenerating S cell and its own distal segment suggests a specific and exclusive recognition of cell type.

The electrical synapse formed by the regenerating neurone on its own distal segment is functionally indistinguishable from a direct fusion with the segment, except that large molecules such as HRP (molecular weight, 40,000) are unable to cross the junction. This raises the possibility that for other systems in which fusion has been invoked to explain rapid and complete regeneration (see refs 15–17 and compare ref. 18), an electrical synapse has also formed.

Knowledge of the exact point of synapse between neighbouring, electrically coupled S neurones in the leech has provided a tool for following a regenerating neurone as it re-establishes a fully functional and structurally intact electrical synapse. In some cases transmission was rapidly restored when the regenerating neurone formed first an electrical synapse with its own severed but still functioning distal axon segment. The segment seems to be an imperfect target for the regenerating neurone, however, for the neurone continues growing along the axon segment to the normal site of synapse, where growth ceases.

We thank Ms Barbara Thomas for technical assistance and Drs Joel Brown, Diana Card, Doug Fambrough, Eric Frank, Skip Hunt, Jan Jansen, Don Kennedy, Jack McMahan and John Nicholls for helpful suggestions. S.C. is supported in part by a U.S. NIH fellowship.

Cross-tolerance between morphine and cholinergic blocking agents microinjected into anterior amygdala

WE have previously demonstrated tolerance to repeated applications of opiates microinjected directly into the amygdaloid region of the brain¹. Since morphine has been shown to inhibit the release of acetylcholine at some brain sites^{2,3}, as well as in the isolated guinea pig ileum^{4,5}, we compared the effect of morphine on amygdala bioelectric patterns with the effects of hemicholinium and scopolamine—two drugs that interfere with cholinergic synaptic activity in different ways. Tolerance that is produced with repeated administration of morphine is associated with cross-tolerance to hemicholinium and scopolamine.

Eighteen rats were anaesthetised with sodium pentobarbital 50 mg kg⁻¹, and bilateral cannula-recording electrode assemblies were implanted in the anterior amygdala. The permanently implanted cannula serves as a guide for

Fig. 1 Development of morphine tolerance to repeated daily microinjections (0.9 µl) of morphine sulphate 10 µg µl⁻¹ (M10) into the anterior amygdala of rat 460. Some recovery of the response was observed when the morphine concentration was increased three times (M30). ▲, M10 dose 1; ★, M10 dose 2; ×, M10 dose 4; ■, M10 dose 9; ●, M30 dose 10; —, no drug.

Fig. 2 Cross-tolerance between morphine 10 µg µl⁻¹ and hemicholinium 5 µg µl⁻¹ microinjected into left anterior amygdala of rat 488. Tolerance to hemicholinium was observed after ten consecutive microinjections. The hemicholinium-tolerant amygdala was also tolerant to morphine. ●, Morphine dose 1; □, hemicholinium dose 1; ▲, hemicholinium dose 10; ○, morphine dose 2 after hemicholinium dose 10.

smaller fluid delivery cannulae and as one pole of the bipolar recording assembly that monitors changes in bioelectrical activity at the injection site. All injections were delivered at a rate of 0.03 µl s⁻¹ for 30 s. In a previous report¹ we showed that analogue recordings from the injection site show spike and wave patterns in response to morphine sulphate but not to injections of saline and dextrophan, the ineffective (+)-isomer of levorphanol. Tolerance developed after repeated daily injections of morphine or levorphanol, whereas no change in morphine sensitivity was observed after repeated injections of saline. The morphine-responsive area was localised to a region ventrolateral to the anterior limb of the anterior commissure. This response to morphine was not observed at injection sites above or below this region or at medial thalamic loci. Haloperidol 6 µg µl⁻¹ had no effect when injected into morphine-responsive sites.

In the present experiment, the analogue recordings were subjected to digital conversion, and the root-mean-square value of EEG amplitude was computed for 5-s epochs taken at successive 5-min intervals before and after the unilateral injections.

To avoid confounding the drug response with high amplitude activity associated with sleep or drowsiness, the rats were maintained on a 22-h water-deprivation schedule. They were trained to consume their normal water intake (approximately 25 ml) by drinking from a water bottle spout that moved into an aperture at one end of the recording chamber on an aperiodic schedule, providing the rat with access to water for 3 s at a time. All the rats learned to consume their daily fluid intake in this manner before the recording sessions were started. Typically, each rat would sit quietly facing the aperture until it was time to drink. This procedure was very effective in providing a means of maintaining a steady EEG baseline throughout the recording session (for example, see Fig. 1).

Microinjections (0.9 µl) of morphine 10 µg µl⁻¹ caused the amplitude of bioelectric activity at the injection site to change from a mean of 567 µV² (s.d. 172) to a mean of 3,982 µV² (s.d. 1,925). This change was statistically significant ($P < 0.01$).

The progressive loss of sensitivity of the amygdala to repeated daily doses of morphine is shown in Fig. 1. Within 10 min after the first injection, the amplitude of the signal at this injection site increased to more than 10

times baseline values and persisted throughout the 45-min recording session. Tolerance, manifested by diminished responsiveness, developed in increments with each successive daily morphine treatment. In the experiment presented in Fig. 1, no observable response to morphine was seen on day 9. Increasing the concentration of morphine to $30 \mu\text{g } \mu\text{l}^{-1}$ on d 10, however, resulted in the reappearance of the morphine response from the tolerant amygdala (Fig. 1).

Cross-tolerance tests between morphine and cholinergic blocking drugs were carried out in 18 animals. In ten animals, tolerance to morphine was established first; in five, tolerance to scopolamine was established and morphine sensitivity was evaluated. Three were first made tolerant to hemicholinium and then tested with morphine. In every case, the first dose given was morphine, followed by a test dose of either scopolamine or hemicholinium.

In tests of cross-tolerance, in which morphine tolerance was first established, cross-tolerance to hemicholinium and scopolamine was found in eight out of ten cases. In two cases the response to scopolamine was reduced but still evident in morphine-tolerant subjects. Tolerance to morphine was observed in every case in which tolerance to scopolamine ($n=5$) and hemicholinium ($n=3$) had been previously established.

An experiment where hemicholinium tolerance was first established is shown in Fig. 2. First, the left amygdala of rat 488 was tested for sensitivity to morphine $10 \mu\text{g } \mu\text{l}^{-1}$ and then to hemicholinium $5 \mu\text{g } \mu\text{l}^{-1}$. A robust response was observed shortly after microinjection of each drug on

successive days. This injection site became tolerant to hemicholinium by the tenth dose of this drug. When the hemicholinium-tolerant injection site was retested for sensitivity to morphine, cross-tolerance to morphine was evident (Fig. 2).

Tolerance to scopolamine is demonstrated in Fig. 3a. The response to morphine before and after the development of scopolamine tolerance is shown in Fig. 3b. When morphine sensitivity was tested at this scopolamine-tolerant injection site, cross-tolerance to morphine was observed (dose 2, Fig. 3b).

Tolerance to morphine and cholinergic blocking drugs is not the result of an irreversible alteration of nerve cells in the anterior amygdala. After tolerance has been acquired, if the injection site is left alone for about 3 weeks, some recovery in the sensitivity to these drugs can be observed. This phenomenon is demonstrated in Fig. 3, in which tolerance to scopolamine and cross-tolerance to morphine was established in the right amygdala of rat 502.

When sensitivity was tested after a 25-d layoff, baseline recordings before injection remained stable, but tolerance to both scopolamine and morphine was no longer evident; the drug response was observed again ($n=3$).

In view of negative findings⁶⁻⁸, it is unlikely that cross-tolerance between opiates and cholinergic blocking drugs could have resulted from a change in the number or affinities of opiate receptor-binding sites.

It is possible that the chronic blockade of synaptic activity by morphine and the cholinergic blocking drugs used in this experiment caused a proliferation of postsynaptic neurotransmitter receptor sites⁹, producing both supersensitivity and cross-tolerance at the injection site. The relationship between disuse supersensitivity and tolerance has been discussed in detail by Jaffe and Sharpless¹⁰, and has been amply demonstrated^{11,12}.

Although cross-tolerance between systemic injections of morphine and muscarinic blocking drugs has been shown previously¹³, this is the first demonstration of symmetrical cross-tolerance between morphine and cholinergic blocking drugs microinjected directly into a discrete brain region.

Electron spin resonance study of membrane protein alterations in erythrocytes in Huntington's disease

HUNTINGTON'S disease (HD), a degenerative disease of the central nervous system inherited as an autosomal dominant trait, is characterised clinically by progressive choreiform movements and dementia¹. Pathological changes include atrophy, severe cell loss and gliosis in the caudate nucleus and putamen and to a lesser extent the globus pallidus and cerebral cortex². The aetiology and pathogenesis of this disease are not understood. Although HD is considered a

defect of the basal ganglia and cerebral cortex, we report here evidence obtained by electron spin resonance (ESR) techniques (methods reviewed in ref. 3) which suggests HD may have more widespread membrane involvement.

Understanding of the basic biochemical defect in HD has not progressed greatly in recent years. Early biochemical studies performed in HD have been reviewed⁴. More recent studies have shown that the inhibitory synaptic transmitter γ -aminobutyric acid (GABA) and a related dipeptide, homocarnosine, were reduced in autopsied HD basal ganglia⁵. Reduced activity of glutamic acid decarboxylase, the enzyme involved in the synthesis of GABA, was found in post-mortem basal ganglia of HD patients⁶. Choline-acetyltransferase, the biosynthetic enzyme for acetylcholine was also reported to be diminished⁶. Other studies have shown elevated levels of ribosomal proteins⁷ and lipofuscin pigment⁸ in HD neurons.

One of the major obstacles to biochemical studies of HD is that the primary alterations which give rise to its characteristic symptoms are found in the basal ganglia and cerebral cortex. Consequently, the availability of significant amounts of fresh, repetitively obtainable, useful specimens for study has been limited. Other uncontrollable factors such as delay in obtaining autopsy tissue, use of various drugs by patients, and super-imposed ageing changes or other pathological alterations have limited the value of such tissue and the enthusiasm of research in this area.

Similar considerations of sample purity and secondary biochemical changes on denervation of muscle led to the study of erythrocyte membranes in several inherited neuromuscular diseases. Our previous spin labelling studies⁹⁻¹⁵ have suggested that myotonic and Duchenne muscular dystrophy and congenital myotonia are diffuse membrane diseases even though muscle is the primary tissue in which symptoms are expressed. An increased membrane fluidity associated with myotonic states⁹⁻¹² and alterations in the membrane protein conformation and/or organisation in dystrophic states¹³⁻¹⁵ were suggested by these spin labelling studies.

We have performed similar ESR experiments with erythrocyte membranes from normal and HD patients. The principal spin label used was 2,2,6,6-tetramethylpiperidin-1-oxyl-4-maleimide (MAL-6) (Syva Associates). MAL-6 has been shown to covalently bind to sulphydryl (SH) groups although a small amount of amino group binding may also occur¹⁶. Fresh, heparinised blood was obtained from 10 patients with well-documented HD from 10 different families. Four of the patients were in the very early stages of the disease, three were in the mid-stages, and three were in the bed-ridden, late stages. Seven of the 10 patients were ambulatory and active. Five of the HD patients were on a regular at-home diet; the other five were on a regular hospital diet. Two of the HD patients were on no medication, two were on diazepam, three were on a butyrophenone and a phenothiazine, and three were on an assortment of medication. Individuals without clinical manifestations or family history of inherited neurological diseases served as controls. Additional ESR studies were undertaken on erythrocyte membranes from patients with non-neurological disorders who were on a butyrophenone and a phenothiazine or diazepam. Intact erythrocytes and erythrocyte membranes (ghosts) were obtained and the spin labelling performed as previously described¹³ except a 1:25 weight ratio of spin label to membrane protein was used. Magnetic resonance experiments were performed on a Magnion-Ventron MVR-9X ESR spectrometer using a quartz aqueous sample cell.

A typical spectrum of erythrocyte ghost membranes labelled with MAL-6 is shown in Fig. 1. Spectra similar to that of Fig. 1 have been previously described as reflective of at least two classes of membrane protein SH groups: one strongly immobilised and the other weakly im-

mobilised¹³⁻¹⁹. The ratio of the spectral amplitude of MAL-6 attached to weakly immobilised SH groups (*W*) to that of MAL-6 attached to strongly immobilised SH groups (*S*) is a convenient monitor of protein organisational and/or conformational changes in membranes¹³⁻¹⁹.

The mean *W/S* ratio values of controls and HD erythrocyte membranes were compared by a two-way analysis of variance²⁰ (Table 1). This two-tailed method of statistical analysis minimises possible fluctuations from day to day between separate experimental values which can often occur with biological samples. *P* is the significance of the difference of mean values of (*W/S*)_{control} and (*W/S*)_{HD} calculated using a two-way analysis of variance. The null hypothesis used was that HD membranes are not different in their physical state compared with that of normal controls. The difference of (*W/S*)_{control} and (*W/S*)_{HD} is significantly less than zero, suggesting an altered conformation and/or organisation of membrane proteins in erythrocytes in HD. In each of the separate experiments represented by the results in Table 1, (*W/S*)_{control} was less than (*W/S*)_{HD}. No alteration in sulphydryl group content of HD could be demonstrated within the sensitivity of the analytical method used²¹.

Fig. 1 Typical ESR spectrum of normal human erythrocyte membrane ghosts labelled with MAL-6. The amplitudes of the $M_I = +1$ weakly and strongly immobilised lines are indicated by *W* and *S*, respectively.

The *W/S* ratio was not altered from control values in erythrocyte ghosts from non-HD patients on diazepam. This parameter of MAL-6 was actually smaller than control values (3.2 compared with 3.7) in erythrocyte membranes from patients without HD who were on a butyrophenone and a phenothiazine. This change is in the opposite direction of the results in HD membranes (Table 1). Other workers have previously reported decreased *W/S* ratios of MAL-6 in bovine erythrocyte membranes on incubation with phenothiazine derivatives¹⁹. These findings together with the fact that some of our HD patients were on no medication, suggest that the increased values of *W/S* in HD (Table 1) are not simply due to drug effects. In addition, the clinical manifestations of HD in the patients in this study ranged from very early mild stages to severe, bed-ridden, late stages. Most were at home, active, and on a regular, normal diet. That the *W/S* ratio was increased in HD compared with normal controls in each experiment suggests that the current results are not due to effects of a particular stage of the disease, diet, or physical activity.

An alteration in the physical state of membrane proteins in erythrocytes in HD has been suggested by these experiments (Table 1). These results may be due to an altered enzyme or other membrane protein, altered amounts of membrane constituents, or altered constituent organisation. An additional possibility may be the presence of a membrane-bound moiety in HD, not found in controls. Experiments designed to discern these possibilities are in progress.

A difference in the conformation and/or organisation of membrane proteins in the basal ganglia like that found in erythrocytes in the present study may possibly give rise to the altered enzymatic behaviour observed in HD (refs 5, 6). Alternatively, the reduced activity of these enzymes in

Table 1 Comparison of ESR spectral amplitudes of MAL-6 attached to weakly immobilised SH groups (W) with that of MAL-6 attached to strongly immobilised SH groups (S) in control and Huntington's disease (HD) erythrocyte membranes

Mean $\pm$ s.e.m. $n = 10$	(W/S) _{control} 3.73 ± 0.11	(W/S) _{HD} 4.26 ± 0.11
	$P < 0.005$	

* P value calculated by a two-way analysis of variance using the null hypothesis that the respective means are equal.

HD may be a secondary consequence of an altered milieu in which they are located. The relationships of the present results to the molecular mechanisms by which the pathological and clinical manifestations of HD arise are unclear, but the alterations in the physical state of erythrocyte membranes which are outside the central nervous system suggest that this disease may be associated with a general membrane abnormality.

Marked enhancement of interferon production in 5-bromodeoxyuridine treated human lymphoblastoid cells

MANY human lymphoblastoid cells produce low levels of interferon spontaneously¹⁻⁵ and this has been attributed to the presence of the Epstein-Barr virus (EBV) in such cells⁶⁻⁷. No clear relationship has been established, however, between the presence of EBV and spontaneous interferon production⁸. Since the latent EBV genome contained in human lymphoblastoid cells can be activated by treatment of these cells with halogenated pyrimidines^{9,10} or inhibitors of protein synthesis¹¹ we determined the effect of 5-bromodeoxyuridine (BrdU) on interferon production in these cells in relation

to the induction of EBV. Previous studies on the effect of halogenated pyrimidines on interferon production have yielded conflicting results ranging from no effect¹²⁻¹⁴ to inhibition¹⁵, or slight stimulation^{15,16}. We report here that BrdU markedly increases both spontaneous and virus-induced interferon production in three human lymphoblastoid cell lines, without any apparent correlation with EBV induction.

The four human lymphoblastoid cell lines studied were chosen for their different characteristics in respect of origin, expression of EBV specified antigens, susceptibility to BrdU induction, and the capacity to produce interferon spontaneously. As reported by others^{4,5}, we found that Namalwa cells produce low levels of interferon spontaneously when maintained at a concentration of 10^7 cells per ml for 24 h (Table 1). Pretreatment of exponentially multiplying cultures of Namalwa cells with BrdU markedly increased the titre of autogenous interferon produced. Maximum titres of spontaneous interferon (160-320 reference units per ml) were obtained after 72 h treatment with BrdU $25 \mu\text{g ml}^{-1}$ (Table 1). (No loss of viability was observed in BrdU treated cultures although the rate of cell multiplication was reduced.)

The spontaneous interferon produced in BrdU-treated cultures of Namalwa cells fulfilled the usual criteria for acceptance of a viral inhibitor as an interferon¹⁷ and was neutralised by a sheep anti-human leukocyte interferon serum. Spontaneous interferon production by Namalwa cells seemed to occur in the absence of EBV induction since no early antigen (EA) or virus capsid antigen (VCA) could be detected by immunofluorescence in either control or BrdU-treated cultures, in accord with other reports^{18,19}.

Raji cells, however, do express EA after treatment with BrdU (refs 17, 18), but have been reported not to produce interferon spontaneously^{2,4,5}. Similarly, we found that no spontaneous interferon was produced in untreated cultures of Raji cells even after 100-fold concentration of the culture supernatants (Table 1). Spontaneous interferon was detected in cultures of Raji cells after 72 h treatment with BrdU, however (Table 1). The spontaneous interferon was neutralised by a sheep antihuman leukocyte interferon serum.

BrdU also increased the amount of interferon produced by Namalwa and Raji cells in response to induction with Newcastle disease virus (NDV). Maximum titres were obtained after either 72 h treatment with BrdU $25 \mu\text{g ml}^{-1}$ or after 24 h treatment with BrdU $100 \mu\text{g ml}^{-1}$ (Table 2). (Treatment with BrdU $100 \mu\text{g ml}^{-1}$ for more than 24 h resulted in considerable cell toxicity.) Treatment of Namalwa cells with BrdU increased, by up to 32-fold, the titre of interferon produced on induction with NDV. A median increase of 8-fold in interferon titre was obtained in a total of 13 determinations (Table 2). Similarly, treatment of Raji cells with BrdU for 48-72 h gave a median increase of 33-fold in the titre of virus-induced interferon production (Table 2). The titres of both spontaneous and virus-induced interferon from BrdU treated cultures remained at the same high levels even when treated cells were subsequently cultivated in the absence of BrdU for 72 h before interferon induction. The continued presence of BrdU during the period of interferon induction did not affect the titre of either spontaneous or virus induced interferon obtained (experiment 4, Table 2). Treatment of Namalwa cells with 5-iododeoxyuridine (IrdU) gave a similar increase to that obtained with BrdU, in the titre of both spontaneous and virus-induced interferon, even though IrdU is a more efficient inducer of latent virus^{19,20}.

Although the mechanism of the enhancement of interferon production by BrdU is unknown, potentiation of interferon production is maximal after prolonged treatment of exponentially multiplying cultures with BrdU, conditions which would be expected to result in incorporation of BrdU into cellular DNA. In addition, the enhancement of

Table 1 Effect of BrdU on spontaneous interferon production and early antigen expression in human lymphoblastoid cells

Lymphoblastoid cells were cultivated in RPMI 1640 medium with 10% foetal calf serum (GIBCO) in stirred suspension culture, for the times indicated, with or without BrdU ($25 \mu\text{g ml}^{-1}$). Each culture was then centrifuged (800g, 15 min), washed once, and the cells resuspended at a concentration of 10^7 cells per ml in the same medium but without BrdU. After 24 h incubation at 37°C in stirred suspension culture, the culture supernatant was harvested by centrifugation (800g, 15 min) and assayed for interferon content after 10-fold concentration with Aquacide (Calbiochem) and dialysis against phosphate buffered saline, pH 7.4. EBV early antigen (EA) was determined on cells at the same time as the culture supernatants were harvested for the assay of interferon. EA was determined on acetone-fixed smears by indirect immunofluorescence using human sera and fluorescein-conjugated goat anti-human IgG globulin (Huntingdon Laboratories, U.S.A.).

Virus-induced interferon production was determined in the same manner as described in Table 1 with the exception that NDV was added to the culture at the concentration indicated. All samples were dialysed at pH 2.0 for 7 d to inactivate residual NDV before assay for interferon.

*Interferon was assayed by inhibition of the cytopathic effect of 100 TCID₅₀ of vesicular stomatitis virus on monolayer cultures of human foreskin fibroblasts as previously described³². Interferon titre expressed as the reciprocal. All interferon titres are expressed in terms of the international reference preparation 69/19 (National Institute of Medical Research, London).

†Sample concentrated 100-fold.

‡To minimise toxicity and increase efficiency of incorporation into DNA, BrdU was added to a culture already multiplying exponentially. Samples concentrated 50-fold.

interferon production by BrdU was reduced when cells were treated with BrdU in the presence of added thymidine, or when BrdU treated cells were exposed to visible light. Incorporation of BrdU into cellular DNA is also known to be necessary for BrdU activation of EBV (refs 20–22). It seems unlikely, however, that EBV induction is responsible for the increase in either spontaneous or virus-induced interferon production in BrdU treated cultures, since this enhancement occurred in Namalwa cells in the absence of EBV induction. Namalwa cells, however, do contain two (probably incomplete) copies of the EBV genome²³. Therefore to exclude the possible involvement of EBV induction we investigated the effect of BrdU on interferon production in the human lymphoblastoid cell line BJAB which does not express the EBV-specified nuclear antigen EBNA and which is negative for EBV by nucleic acid hybridisation²⁴. Spontaneous inter-

feron was detected (after 50-fold concentration) in the culture supernatants from BrdU treated BJAB cells, but not in the supernatants from untreated control cultures (Table 1). The spontaneous interferon produced was neutralised by a sheep anti-human leukocyte interferon serum. There was also a clear cut increase in NDV-induced interferon production in BrdU treated BJAB cells (Table 2). No EA or VCA was detected either before or after treatment of BJAB cells with BrdU. These results strongly suggest that induction of EBV by BrdU is not responsible for the observed increase in interferon production in BrdU treated cultures.

Namalwa, Raji and BJAB are all B-lymphocyte derived cell lines^{18,24}. It was therefore of interest to determine the effect of BrdU on the T-lymphocyte cell line JM²⁵. The JM cell line did not produce interferon spontaneously either

‡Culture not washed after removal of BrdU.

before or after treatment with BrdU. In addition, treatment of JM cell with BrdU ($25 \mu\text{g ml}^{-1}$) decreased the titre of interferon produced in response to induction with NDV. It remains to be determined whether the behaviour of JM cells is characteristic of T cells in general. Preliminary results suggest that BrdU also increases NDV-induced interferon production in a non-lymphoid Moloney sarcoma virus transformed mouse cell line (C 243-3 cells), but not in a line of human or rat fibroblasts.

BrdU uniformly incorporated into cellular DNA has been reported both to increase²⁶ and to selectively inhibit²⁷ the transcription of certain genes in mammalian cells. Interferon induction is sensitive to actinomycin D²⁸ and represents a process analogous to enzyme induction²⁹. Two possible explanations of our results would be that either BrdU increases the transcription of the interferon messenger or inhibits the transcription of an inhibitor of interferon synthesis.

Human lymphoblastoid cells (and in particular the Namalwa cell line) have received attention as a source of human interferon for clinical trials^{30,31}, since these cells can be cultivated in suspension culture in virtually limitless quantity.

Our results show that up to a 32-fold increase in interferon titre can be obtained by treatment of Namalwa cells with BrdU. Furthermore, higher interferon titres can be obtained from BrdU-treated cultures of Namalwa cells, inoculated with considerably less virus inducer than from untreated cultures induced with optimal amounts of NDV (Table 2, experiment 4). We believe that these results may therefore be of considerable importance for the large scale production of human interferon.

We thank Dr Gilbert Lenoir for helpful suggestions and for the gift of the BJAB and JM cell lines, Dr Guy de Thé for the EBV-specific human sera, Dr Kari Cantell for sheep anti-human leukocyte interferon serum, Dr Hans Strander for Namalwa cells, and Dr Pierre Verroust for Raji cells. This work was supported by the Délégation Ministérielle, Direction des Recherches et Moyens d'Essais and by the CNRS.

Stimulation of prostaglandin E production in cultured human fibroblasts by poly(I) · poly(C) and human interferon

PROSTAGLANDINS (PGs) have emerged as one of the principal mediators of the inflammatory process¹⁻³. Elevation of tissue concentration of PGs was noted following inflammation^{3,4}, or treatment with various hormones^{5,6}, cyclic nucleotides (ref. 7 and U.Z., B. Strulovici and H.R.L., in preparation), serum⁸, drugs^{8,9} and antigen¹⁰. The beneficial effects of anti-inflammatory drugs have been correlated with their ability to suppress PG production either by curtailing precursor availability (glucocorticosteroids^{11,12}) or by inhibiting PG synthetase activity (non-steroidal drugs¹). Viral infections are associated with interferon production¹³ and with inflammation¹⁴. Little is known about the possible involvement of interferon in the inflammatory reaction, though it has been suggested that interferon may have anti-inflammatory properties¹⁵. It has been shown that an interferon inducer, double-stranded polyinosinate-polycytidylic acid [poly(I)·poly(C)], as well as human interferon, stimulate hyaluronic acid production by human synovial fibroblasts in culture¹⁶. Overproduction of hyaluronic acid is known to be associated with the inflammatory process¹⁴; the effect is prevented by cortisol or indomethacin¹⁶. We report here the stimulation by poly(I)·poly(C) and by human interferon of prostaglandin E (PGE) production by human synovial and foreskin fibroblasts in culture. Cortisol inhibited this effect.

Fibroblasts derived from synovial membranes of patients undergoing surgery for meniscus tear were grown in culture using methods described by Castor *et al.*¹⁷. Human fibroblast interferon (2×10^4 U ml⁻¹) was prepared from foreskin fibro-

Fig. 1 Time course of stimulation of PGE production in cultured synovial fibroblasts by poly(I)·poly(C) and human interferon. Synovial fibroblasts were sown (about 4×10^5 cells per ml) in a medium containing Parker CMRL-1066 (80%), heat-inactivated human serum (10%) and foetal calf serum (10%), supplemented by L-glutamine, penicillin and streptomycin, and grown as monolayers. Samples of the medium were withdrawn after the time-intervals indicated for PGE determination. Δ , Controls; $\bullet$, poly(I)·poly(C) added to the medium ($100 \mu\text{g ml}^{-1}$); $\circ$, human fibroblast interferon added (100 U ml⁻¹).

blasts (FS4) by the method of Havell and Vilcek¹⁸. Partially purified human lymphoblastoid interferon (purification about 200-fold) was prepared as described by Anfinson *et al.*¹⁹. Poly(I)·poly(C) (Miles) or interferon were incubated with the synovial fibroblast and foreskin cell cultures for various times and the accumulation of prostaglandins of the E group in the medium was determined by radioimmunoassay as previously described²⁰.

Both poly(I)·poly(C) ($100 \mu\text{g ml}^{-1}$) and human interferon (100 U ml^{-1}) stimulated PGE production by synovial fibroblasts: increased accumulation of PGE in the medium was noted within 3 h and a peak was reached at 24 h (Fig. 1). Mouse interferon did not stimulate PGE production in these human cells. The lowest effective concentration of poly(I)·poly(C) was $10 \mu\text{g ml}^{-1}$ and the response was maximal at $20\text{--}100 \mu\text{g ml}^{-1}$ (Fig. 2). Single-stranded polyinosinate (poly I) or polycytidylate (poly C) or polyadenylate-polyuridylylate [poly(A)·poly(U)] did not stimulate PGE production when added to cultured synovial fibroblasts at $100 \mu\text{g ml}^{-1}$. Poly(I)·poly(C) did not induce PGE production

Fig. 2 Dose-response curve of stimulation of PGE production in cultured human synovial fibroblasts by poly(I)·poly(C). PGE concentration in the medium was determined by radioimmunoassay. Vertical bars, s.e.m. ($n = 8$). For experimental details see Fig. 1 legend.

in cultured human peripheral blood lymphocytes, which are known not to respond to double-stranded RNA with interferon production. In contrast, human interferon and poly(I)·poly(C) stimulated PGE production in two lines of human foreskin fibroblasts tested (FS7 and FS4). Stimulation was proportional to the amount of interferon added (Fig. 3). Both fibroblast and lymphoblastoid human interferon stimulated PGE production in foreskin cells. Addition of partially purified lymphoblastoid interferon to the medium (100 U ml^{-1}) elicited a 40-fold stimulation of PGE. Cycloheximide ($10 \mu\text{g ml}^{-1}$) and actinomycin D ($2 \mu\text{g ml}^{-1}$) prevented the stimulation by poly(I)·poly(C) of PGE formation (data not shown). The stimulatory action of poly(I)·poly(C) and of interferon on PGE production by foreskin fibroblast cultures was also abolished by concomitant addition of cortisol ($2 \mu\text{g ml}^{-1}$) to the medium (Fig. 4). Both poly(I)·poly(C) and human interferon had a moderate (30%) inhibitory effect on synovial fibroblast proliferation and cortisol prevented this effect (data not shown).

This is the first report to show that interferon is capable

Fig. 3 Dose-response curve of stimulation of PGE production by human foreskin fibroblast interferon in human foreskin fibroblast cultures. The cells (2×10^6 cells per ml) were sown in Eagle's MEM medium containing 5% heat-inactivated foetal calf serum and penicillin and streptomycin and incubated for 24 h at 37°C with various doses of interferon. PGE was determined by RIA. Bars represent mean $\pm$ s.e.m.

of stimulating the production of PGE, an established mediator of inflammation¹⁻³. This effect shares the known species specificity of interferon action, since only interferons of human origin, but not mouse interferon, induced PGE synthesis in human fibroblast cells. The efficacy of partially purified lymphoblastoid interferon makes it unlikely that the observed effect was due to contaminating

Fig. 4 Prevention by cortisol (Cort; $2 \mu\text{g ml}^{-1}$) of the stimulatory effect of poly(I)·poly(C) [(I.C.)_n; $100 \mu\text{g ml}^{-1}$] and human fibroblast interferon (IF; 100 U ml^{-1}) on PGE production by human foreskin fibroblasts. Con, control. Other experimental details as for Fig. 3.

material. This study shows that poly(I)-poly(C), which induces interferon formation in synovial and foreskin fibroblasts¹⁶⁻¹⁸, is also capable of stimulating PGE production. Poly(A)-poly(U) and single-stranded poly(I) or poly(C), which do not induce interferon formation, are not active in this respect. The induction of PGE synthesis by either interferon or poly(I)-poly(C) has a latency of about 3 h. During this time both RNA and protein synthesis are required.

Cortisol, a well known anti-inflammatory drug, which is able to reduce PGE production by inflamed synovial membrane^{12,21}, abolished PGE production induced by both interferon and poly(I)-poly(C). We suggest that interferon may have a role in propagating the inflammatory effect of viral infections through prostaglandins, which have been shown to participate in the body's general defence mechanism²². It is of interest that both glucocorticoids and aspirin seem to enhance the pathogenic effects of viral infections^{23,24}. The present findings are difficult to reconcile with those of Koltai and Mecs¹⁶, who have attributed to the interferon inducer, poly(I)-poly(C), an inhibitory effect on inflammation.

Another common effect of interferon and prostaglandins of the E type is their potent inhibition of the replication of several cell types²⁵⁻²⁷. Cortisol and indomethacin, which inhibit PGE production^{1,11,12,21}, stimulated tumour cell replication²⁸ and prevented the inhibitory effect of interferon on synovial fibroblast growth. The significance of prostaglandin synthesis in the mode of action of poly(I)-poly(C) and interferon as antiviral and anti-tumour agents is not yet clear and is under further study.

Virus-like particles from both control and scrapie-affected mouse brain

CHO and Grieg¹ reported that 14-nm virus-like particles could be extracted from the brains of mice in the late clinical stage of scrapie but not from the brains of young, uninoculated mice. The extraction procedure involved repeated fluorocarbon treatment followed by equilibrium banding on CsCl gradients. One band was obtained from extracts of normal brain at a density of 1.29-1.30 g cm⁻³ and two bands were obtained from scrapie brain extracts at densities of 1.29-1.30 g cm⁻³ and 1.33-1.34 g cm⁻³, respectively. Electron microscope studies showed that 14-nm particles were found mainly in the 1.33-1.34 g cm⁻³ fraction derived from scrapie brains. It was subsequently reported² that similar particles could be obtained at the same density after centrifuging extracts of scrapie hamster brain. This second study also showed that the exhaustive extraction procedure resulted in a large loss of infectivity, but the small amount of infectivity remaining sedimented mainly in the same position as the 14-nm particles. From these observations it was suggested that the 14-nm particles might be the causative agent of scrapie. Similar studies have been carried out at Compton during the last year in an attempt to repeat these findings with brain both from mice in the late clinical stage of infection and from sheep with natural scrapie. In none of these studies was a visible band seen at 1.33-1.34 g cm⁻³ after isopycnic centrifugation in CsCl. Electron microscopy studies of this fraction derived from scrapie mice showed 14-nm particles, resembling those originally reported, in one field only; the sample was rich in other particulate material common to control samples also. In order to resolve these different findings a collaborative study was arranged at Lethbridge in which scrapie mouse brain and brains of age-matched control mice (previously injected with normal mouse brain) from both Institutes were extracted. We report here that 14-nm particles can be visualised from both control and scrapie-affected mouse brain.

Four groups of mice were used. Two groups of female, random bred, Swiss white mice of the Animal Diseases Research Institute (Western) Lethbridge were inoculated intracerebrally with 0.03 ml of a 1% (wet weight) suspension of mouse brain in physiological saline; the control group was injected with a suspension of normal mouse brain and the scrapie group with a suspension of brain from clinically-affected mice. The other two groups were specific pathogen free, female, Compton white mice injected in an identical manner. The Lethbridge mice were infected with the Compton strain of mouse-adapted scrapie obtained from Dr W. J. Hadlow³ and the Compton mice were infected with the same strain⁴, passaged at Compton. Scrapie mice were killed in the late clinical stage of the disease (after 18 weeks) and the brains collected and stored frozen (-20 °C). Control brains were collected at the same time. The brain samples from Compton were coded by an independent observer before being taken to Lethbridge. The weights of the various brain pools used for extraction were as follows: 97 g of control brain and 80 g of scrapie brain from Compton, 123 g of control brain and 175 g of scrapie brain from Lethbridge. The method of extraction used was the same as originally described¹. After the extensive Freon extraction procedure, material equivalent to 12 g of original brain in a volume of 1.0 ml was centrifuged on a CsCl gradient in a Spinco 50.1 Ti Sw Rotor at 243,000g for 72 h.

After centrifugation of the Lethbridge control sample only one distinct band was seen in the CsCl gradient, at a density of 1.29-1.30 g cm⁻³, whereas the Lethbridge scrapie sample gave two bands, one identical to the control and an additional, faint band which was seen at a density of

1.33–1.34 g cm⁻³. Centrifugation of both Compton samples (normal and scrapie) gave less distinct bands with most of the material sedimenting to a density of 1.29–1.30 g cm⁻³. Ten equal fractions of 0.45 ml were collected from all four samples by syringes from the side of the tube and each fraction was subsequently examined under the electron microscope as described before¹ at both Compton and Lethbridge.

At Lethbridge spherical particles similar to those originally described by Cho and Greig¹ were seen at a density of 1.33–1.34 g cm⁻³ from both the control and both the scrapie extracts. The particles were morphologically similar from all four sources. At Compton very few particles were seen in the projected size range in any of the four samples; however, conditions of storage may have accounted to some extent for these different observations at the two centres. The evidence indicated that, where particles were seen, they were present in both scrapie and control preparations.

These findings suggest that the particles were either of host origin or, alternatively, represent an unknown species of virus which is present in both normal and scrapie-affected mice. The former possibility is considered more likely since similar particles have also been obtained from the brains of scrapie-affected hamsters² and goats (H.J.C. unpublished).

Since 14-nm particles can be obtained from both control and scrapie-affected brain, it seems that they are not specifically associated with scrapie. The scrapie infectivity reported to be present at a density of 1.33–1.34 g cm⁻³ may therefore be associated with some entity other than the 14-nm particles. Alternatively, it is possible that although the particles obtained from both control and scrapie mice were morphologically similar, there may be biochemical differences; for example the 14-nm particles from scrapie brain might harbour a scrapie-specific nucleic acid. This possibility can be tested by a detailed analysis of the biochemical components present in highly purified preparations of 14-nm particles from several sources. Some preliminary, immunological studies have already been carried out involving treatment of 14-nm particles from scrapie mouse brain with anti-mouse ferritin serum prepared in rabbits. Aggregation of the 14-nm particles was observed by electron microscopy indicating that the particles isolated from scrapie brain share common antigen(s) with mouse ferritin (H.J.C. and Darcel, unpublished).

We are grateful to the Multiple Sclerosis Society for the provision of funds to Dr G. D. Hunter, whom we thank for encouragement and advice. We thank Miss Carol Walker and Miss Janice Robinson for technical assistance and Miss S. Becker and Dr M. S. Shahrabadi in assisting with the electron microscopy. Dr L. D. Miller kindly provided the scrapie goat brains.

Role for nucleocapsid protein phosphorylation in the transcription of influenza virus genome

LIKE other minus-strand RNA viruses^{1–3}, influenza virus seemed to contain protein kinase as well as viral transcriptase in, or in association with, nucleocapsid structure⁴. The kinase phosphorylates NP-protein constituting the nucleocapsid, but none of the other virion proteins in *in vitro* reaction⁵. Since the influenza virus RNA serves as a template for transcription in the form of nucleocapsid in which the viral RNA is tightly packed in helical array of NP-protein^{7–9}, it is tempting to implicate the NP-protein phosphorylation in the control of viral transcription. We report here that the phosphorylation of NP-protein stimulates viral transcription, and that some conformational changes in the nucleocapsid may be involved in the stimulation of transcription.

Influenza A₂ virus (R1/57/57) was grown in embryonated eggs and purified as described previously⁶. None of the viral proteins was phosphorylated to a significant extent during virus growth in eggs⁶. The purified virus suspension was divided into two portions, one of which was phosphorylated with the endogenous protein kinase as described (legend to Fig. 1). In these conditions, only NP-protein of the virion proteins was phosphorylated and its phosphate-accepting sites were saturated within 20 min (ref. 6). The phosphorylated nucleocapsid was then isolated and made free of ATP (legend to Fig. 1). Since it was crucially important to confirm complete removal of ATP from the nucleocapsid, the other portion of the nucleocapsid preparation was treated in the same manner as the first, except that ATP was added at the end of incubation and then removed as above. This unphosphorylated preparation will be referred to as 'native nucleocapsid'. A separate experiment in which ¹⁴C-ATP was incubated with the nucleocapsid and then removed by the same procedure, showed that a residual amount of free ATP, if any, was less than 10⁻⁶ of the input amount, which for our purposes was negligible. The nucleocapsid preparations thus obtained were practically free of neuraminidase and haemagglutinin as determined by gel electrophoresis, but contained a considerable amount of matrix (M) protein and a few minor components (one of which may correspond to viral transcriptase), in addition to NP-protein.

A comparison of circular dichroism (CD) spectra of the native and the phosphorylated nucleocapsid is given in Fig. 1a. Phosphorylation caused a significant reduction in negative ellipticity in the range 200–250 nm, suggesting the reduction of secondary structure content in the protein moiety of nucleocapsid. This conformational change seemed reversible. Thus, the treatment of phosphorylated nucleocapsid with protein phosphatase¹⁰ could remove 80% of the phosphate which had been introduced by the *in vitro* phosphorylation and the CD spectrum of the dephosphorylated nucleocapsid was indistinguishable from that of native one (Fig. 2b). The phosphorylation-induced conformational changes were also reflected in the increased heat lability of the nucleocapsid (insert Fig. 1).

To determine the effect of protein phosphorylation on the nucleocapsid-directed transcription, transcription had to take place in the absence of phosphate donor for protein kinase¹¹ and in the present study this was accomplished by using an ATP analogue, β - γ -imido-ATP or AMPPNP (ref. 11). This analogue can be used, although less efficiently, as a substitute for ATP for the viral transcription, but it will not serve as phosphate donor for protein kinases¹¹.

When the native or phosphorylated nucleocapsid was incubated in the ordinary reaction mixture for transcription

(ATP present), the kinetics of the transcription were similar to each other, indicating that the transcriptional activities of both the preparations were equally preserved during the preceding treatment (Fig. 2). In contrast, when transcriptional activities were assayed in a reaction mixture in which ATP was replaced by AMPPNP and therefore free of phosphate donor for protein kinase, the native nucleocapsid exhibited two-phase kinetics of transcription; the reaction rate was significantly low for the first 3 h and then increased. This was observed consistently in six separate

Fig. 1 Comparison of the native and phosphorylated nucleocapsids in CD spectra and in denaturation temperatures. *a*, Purified influenza A₂ virions (3.2 mg protein) were incubated in 3 ml of the mixture for phosphorylation reaction containing 0.1 mM ATP, 8 mM Mg²⁺, 10 mM dithiothreitol (DTT), 0.1% Nonidet-P40 and 10 mM Tris-Cl (pH 8.0) at 32 °C for 30 min. The mixture was cooled in ice and overlayed on a 10% sucrose solution containing 25 mM Tris-Cl (pH 8.0), 1 mM Mg²⁺, and 0.5 mM DTT, and centrifuged at 4 °C and 100,000g for 100 min to pellet the nucleocapsid. The pellet was resuspended and pelleted again through the sucrose solution to remove residual ATP completely. The final nucleocapsid pellet was resuspended in 25 mM Tris-Cl (pH 7.4) to give 0.35 mg protein ml⁻¹ and subjected to the CD spectra determination at 20 °C. The native nucleocapsid was prepared similarly except that ATP was added after the incubation and then removed as above. CD spectra were determined in a Jasco J-20 automatic spectropolarimeter. —, Native nucleocapsid; ---, phosphorylated nucleocapsid. In the range 210–260 nm, the mean ellipticity θ is expressed in deg cm² dmol⁻¹ of amino acid residue (assuming a mean molecular weight of an amino acid as 103) and in the range 260–290 nm deg cm² dmol⁻¹ of nucleotide residue (assuming a mean molecular weight of a nucleotide as 330). *b*, The phosphorylated nucleocapsid described in *a* (2.0 mg protein) was incubated in 5 ml of a mixture containing 10 mM sodium acetate, pH 5.8, 5 mM L-ascorbic acid and 125 μ g protein of partially purified protein phosphatase from bovine spleen¹⁰ at 37 °C for 1 h. The nucleocapsid was then pelleted by sedimentation through the sucrose solution as above and resuspended in 25 mM Tris-Cl (pH 7.4) to give 0.35 mg protein ml⁻¹ for the CD spectrum determination. —, Native nucleocapsid; ---, dephosphorylated nucleocapsid. Inset, Hyperchromicity determinations at 260 nm during temperature rise at 0.5 °C min⁻¹.

Fig. 2 Transcriptional activities of the native and phosphorylated nucleocapsids in the presence or absence of phosphate donor. The reaction mixture (lacking phosphate donor) contained, in 1.0 ml, 0.1 mM each of AMPPNP, CTP and GTP, 0.2 μ M (20 μ Ci) of ³H-UTP, 8 mM Mg²⁺, 1 mM Mn²⁺, 80 mM NaCl, 5 mM DTT, 10 mM Tris-Cl (pH 8.2) and 2.4 mg protein of the influenza virus nucleocapsid; and was incubated at 33 °C. Aliquots were taken in duplicate at the times indicated and the trichloroacetic acid-insoluble radioactivities were determined in a scintillation spectrometer. In another reaction mixture (containing phosphate donor), AMPPNP was replaced by 0.1 mM of ATP. ●, Phosphorylated nucleocapsid; ○, native nucleocapsid; —, with AMPPNP as substrate; ---, with ATP as substrate.

experiments with different preparations of native nucleocapsid, but such reaction lag was not seen with the several preparations of phosphorylated nucleocapsid. We interpret the results as indicating that the phosphorylation of NP-protein leads to the stimulation of viral transcription. It is conceivable that the conformational change induced by the phosphorylation is involved in the stimulation mechanism. Such stimulation by the previous phosphorylation of nucleocapsid was undetectable in the ordinary transcription system containing ATP, presumably because the phosphate-accepting sites of NP-protein were rapidly saturated in the beginning of transcription reaction⁹.

To examine whether the late recovery of transcription with the native nucleocapsid in the absence of ATP resulted from very slow phosphorylation of the nucleocapsid using CTP, UPT or GTP present, the CD spectra of native nucleocapsid were measured at various times during the transcription. The CD spectrum change below 250 nm which was characteristic to the phosphorylation of nucleocapsid (Fig. 1) was not seen; however, instead, a marked ellipticity change was observed in the range 270–280 nm at about 3 h of incubation (spectra not shown). The ellipticity change at 273 nm as a function of incubation time was plotted (Fig. 3) and the results indicated that the nucleocapsid underwent conformational rearrangement (possibly the changes in RNA-protein interaction) which was distinct from the conformational change caused by phosphorylation of NP-protein, and that the time of rearrangement coincided with the start of late stimulation of transcription. Since this rearrangement also occurred in the absence of nucleotidetriphosphates (Fig. 3c), it was neither the consequence of transcription nor of phosphorylation. Although it is

Fig. 3 The ellipticity changes at 273 nm during the transcription with native nucleocapsid. The native nucleocapsid (1.1 mg) was incubated in a CD measuring cell at 33 °C in a final volume of 1.3 ml of the reaction mixture for transcription (lacking phosphate donor) described in Fig. 2. The concentrations of AMPPNP, GTP and CTP were reduced to 0.01 mM so that the CD spectra could be read directly during the incubation. At the times indicated 20 μ l aliquots were withdrawn for the determination of ³H-UTP incorporation into the trichloroacetic acid-insoluble fraction (transcription, — — —), immediately after which the CD spectra were determined and the ellipticities at 273 nm were plotted (a), — — —. Each CD measurement took about 10 min and this time was not included in the total incubation time. b, The ellipticity change at 273 nm incubated in the reaction mixture which contained ATP instead of AMPPNP. c, The ellipticity change at 273 nm incubated in the reaction mixture from which all the nucleotidetriphosphates were omitted.

unknown at present whether this conformational rearrangement is an artefact due to the long incubation of isolated nucleocapsid, the result supports the concept that the native influenza virus nucleocapsid must undergo some conformational changes in order to be transcribed efficiently. This effect is not observed, however, in the ordinary transcription reaction using ATP, or in the reaction with prephosphorylated nucleocapsid using AMPPNP because the transcription is stimulated more effectively by the phosphorylation of nucleocapsid with the endogenous protein kinase.

3' Terminal sequences of 16S rRNA do not explain translational specificity differences between *E. coli* and *B. stearothermophilus* ribosomes

DIRECT Watson-Crick base pairing between the 3' terminus of 16S RNA and messenger RNA seems to contribute to the recognition and binding of protein synthesis initiator regions by *Escherichia coli*^{1,2}. Since bacterial species differ in the pyrimidine-rich sequences at the 3' termini of their 16S RNAs, it has been suggested that this mRNA-rRNA interaction can account for observed differences in translational specificity among prokaryotes³. To test this hypothesis, we have asked whether it explains the choice of sites bound by *Bacillus stearothermophilus* ribosomes in two mRNAs—the R17 and Q β phage genomes. The RNA sequence data presented here lead to two conclusions. First, *B. stearothermophilus* ribosome recognition of two non-initiator Q β regions at high temperature⁴ is indeed correlated with an extensive mRNA-rRNA match. Second, surprisingly, the 3' terminal sequence of 16S rRNA from *B. stearothermophilus* is identical to that of *E. coli*⁵⁻⁷ except that the 3' terminal adenosine of *E. coli* rRNA is replaced by UCUA_{OH} in the thermophile. Thus, rRNA sequences at the 3' end of 16S rRNA cannot explain differences in the capacity of ribosomes from these two species to recognise RNA phage initiator regions at lower temperatures^{4,8,9}.

The translational specificity of ribosomes from *B. stearothermophilus* has previously been studied both at elevated temperatures (60-70 °C), where protein synthesis in this organism is optimal, and at a lower temperature (49 °C) where these ribosomes can be directly compared with those of *E. coli*. At 65 °C *B. stearothermophilus* ribosomes bind efficiently to the A protein initiator region in R17 RNA, while discriminating against the other two phage cistrons^{4,10} (Table 1). In Q β RNA none of the three normal initiation sites is bound by *B. stearothermophilus* ribosomes at high temperature. Instead, two non-AUG- or GUG-containing regions, one of which is recovered as a 35-nucleotide fragment (the typical size of ribosome-protected regions) and the other as a simple purine-rich nonanucleotide, are selected⁴. At a lower temperature (49 °C), where *E. coli* ribosomes strongly bind all three initiator regions in R17 RNA, *B. stearothermophilus* ribosomes retain good binding of the R17 A site and recognise the R17 replicase initiator region only weakly¹¹. With Q β RNA at 49 °C, the coat and replicase initiators are bound, but with much lower efficiency than when *E. coli* ribosomes are used to protect the same RNA¹¹. In addition, the non-initiating Q β sites bound at 65 °C by *B. stearothermophilus* ribosomes are nearly absent at 49 °C (ref. 11 and M. L. Goldberg and J. A. S., unpublished). A reasonable explanation for their disappearance is masking by RNA secondary structure existing at this temperature. Evidence that secondary structure can indeed sequester potential ribosome binding sites comes from observations on the RNA bacteriophage RNAs, where either fragmentation¹²⁻¹⁴ or unfolding with formaldehyde^{15,16} increases ribosome recognition of both authentic and spurious initiation sites in these mRNAs.

We began by asking whether the sites in R17 and Q β RNA which are selected by *B. stearothermophilus* ribosomes at 65 °C are related to each other in having a particularly high degree of complementarity to the 3' terminal sequence of *B. stearothermophilus* 16S RNA. The partial sequence data previously available^{4,17,18} suggested that this might be the case, but resolution of ambiguities remaining in the sequence of the Q β non-initiating sites as well as extension of the *B. stearothermophilus* 16S

Data were obtained from ribosome-mRNA binding experiments carried out at 65 °C (ref. 4) or at 49 °C (ref. 11). The mRNA sequences represent only the 5' terminal portions (including the AUG initiator triplet) of the bound sites. They are arranged so that the regions complementary to 16S rRNA are aligned. Italics indicate that portion of the *B. stearothermophilus* 16S rRNA sequence which differs from *E. coli*. At each temperature, all sites bound are shown. Since the Q β A site was not recognised by *E. coli* ribosomes tested in parallel at 49 °C, it is presumed that this region was masked at this temperature (as it is at 37 °C (ref. 13)) and unavailable for binding by *B. stearothermophilus* ribosomes (M. L. Goldberg and J.A.S., unpublished). The melting temperatures (T_m) of the mRNA-rRNA complexes were calculated according to the rules for base stacking interactions and for the formation of double helical structures in bimolecular reactions (ref. 26 and R. C. Yuan, personal communication). For this analysis, the complexes were drawn without bulge loops since the thermodynamic parameters for loop structures are less accurately known than are those for structures without loops. The R17 coat site-rRNA complex can be drawn with a bulge loop in an alternative configuration whose calculated T_m is higher than the value shown. The fact that the calculated T_m values fall below the temperatures at which ribosome binding is actually observed indicates that other molecular interactions on the ribosome contribute greatly to the stability of mRNA-ribosome complexes. In the cases where the T_m values of isolated mRNA-colicin fragment complexes have been measured, there is good agreement between the theoretical and experimental values²¹.

terminal sequence was required to reach a definite conclusion. Accordingly, we determined the nucleotide sequences of the two polypurine tracts in the Q β non-initiators and the entire 3' terminal T1 oligonucleotide from *B. stearothermophilus* 16S RNA.

Since only the polypurine tracts from the Q β fragments were required for analysis, we avoided ribosome binding as an isolation procedure and instead took advantage of the large size and unique composition of these oligonucleotides. We isolated them directly from a total pancreatic ribonuclease digest of ³²P-labelled Q β RNA after fractionation in two dimensions (see legend to Fig. 1). The 3' terminal T1 oligonucleotide of *B. stearothermophilus* 16S rRNA, also ³²P-labelled, was isolated by selective adsorption to dihydroxyboryl cellulose¹⁹. Sequences of all three oligonucleotides were deduced primarily by partial digestion with spleen phosphodiesterase, as shown in Fig. 1. Additional data required to establish the sequence of the 16S terminus was obtained by standard techniques²⁰ as detailed in Table 2.

The sequences presented in Table 1 show that the two Q β non-initiator regions and the R17 A site do indeed exhibit extensive complementarity to *B. stearothermophilus* 16S rRNA. The Q β non-initiators (oligonucleotides *a* and *b* in Table 2) can pair with the 3' end of *B. stearothermophilus* 16S RNA to yield a structure which is nearly as stable as the complex formed between the R17 A site and the *B. stearothermophilus* 16S terminus. This latter complex is calculated to be identical in stability to the R17 A site-*E. coli* rRNA duplex, which has recently been isolated and characterised^{2,21}. In contrast, complexes between the *B. stearothermophilus* 16S terminus and other R17 and Q β initiators are theoretically much less stable (Table 1), a property which may explain their inability to be bound by thermophilic ribosomes at high temperatures.

On the other hand, Table 1 also demonstrates that species-related differences in the degree of mRNA-rRNA complementarity cannot explain the mRNA binding preferences of thermophilic ribosomes when *E. coli* and *B. stearothermophilus* ribosomes are compared at 49 °C.

*The expected product, UA_{OH}, was not conclusively identified in these digests, presumably because it was obscured by the streaking of U₃C.

Fig. 1 Partial spleen phosphodiesterase digestion products of Q β non-initiator fragments (a and b), and of the 3' terminus of *B. stearotherophilus* 16S rRNA (c). ^{32}P -labelled Q β RNA was prepared as previously described²⁷. *B. stearotherophilus* ^{32}P -labelled 16S RNA was isolated from late log phase cells grown at 65 °C in 50 ml of low-phosphate medium containing 4 mCi of $^{32}\text{PO}_4$ (New England Nuclear). The growth medium was that described in reference 27, but was buffered with 0.02 M bis-Tris (Sigma), pH 7.0, and was supplemented with 1/20 volume of R broth¹¹ and with trace elements¹¹. RNA was extracted with hot sodium dodecyl sulphate (SDS) and phenol after treatment of cells with lysozyme and EDTA²⁸. 16S RNA (specific activity c.p.m. $2 \times 10^5 \mu\text{g}^{-1}$) was isolated by sucrose density gradient centrifugation. The sequences of the Q β polypurine tracts were determined by partial digestion with the 5' exonuclease, spleen phosphodiesterase. The fragments were isolated from a total pancreatic ribonuclease digest of Q β RNA after fractionation in two dimensions: (1) electrophoresis on cellophel (Kalex) at pH 3.5; (2) homochromatography on DEAE thin layer plates (Analtech) with homomixture C diluted 1:1 with 8 M urea²⁰. To obtain reproducible digestion conditions for spleen phosphodiesterase, unlabelled RNA derived from the homomixture was removed from eluted oligonucleotides by chromatography on DEAE thin layers (Macherey-Nagel) with 1.5 M pyridinium formate containing 7 M urea²⁰. After elution with 30% triethylamine carbonate, pH 10, (without carrier RNA), the radioactive oligonucleotides were digested with 10 μl of 0.17 mg ml⁻¹ spleen phosphodiesterase (highly purified preparation, a gift from E. G. Niles) in 0.1 M ammonium acetate, pH 5.7, 0.002 M EDTA, 0.05% Tween 80 in the presence of 30 μg unlabelled rRNA at 37 °C. Aliquots were removed at 0, 1, 2, and 3 h and immediately frozen. Digestion products in the pooled aliquots were fractionated by electrophoresis on cellophel at pH 3.5 in the first dimension (right to left in the figure), followed by homochromatography with 1:1 diluted homomixture C²⁰ on Analtech DEAE thin layer plates in the second (bottom to top in the figure). The sequences shown above were deduced from the first dimension mobility shifts produced by the loss of a single nucleotide, and were confirmed by further digestion of each oligonucleotide with T₁ ribonuclease. Sequence analysis of the *B. stearotherophilus* 16S 3' end used the terminal T₁ oligonucleotide eluted from dihydroxyboryl cellulose¹⁹. Taken together with the results of Shine and Dalgarno¹⁸ (underlined sequence), data shown in Table 1 establish the sequence GAUCAC (Py $\sim$) UCCUUUCUA_{OH}. Partial digestion with spleen phosphodiesterase of both the largest fragment produced by U₂ digestion [C(Py $\sim$) UCCUUUCUA_{OH}, shown in c] and the intact T₁ product (not shown) establish the sequence: GAUACCUC CUUUCUA_{OH}. Spleen phosphodiesterase digestion conditions were as described for the Q β fragments, except that 6 μg of carrier ribosomal RNA was used. The products were fractionated as described above for the Q β oligonucleotides, and were analysed by digestion with pancreatic ribonuclease (0.6 mg ml⁻¹, 2 h, 37 °C, in 0.01 M Tris-HCl, pH 7.5) after derivatisation with carbodiimide²⁰.

While initial work indicated that the *B. stearotherophilus* 16S terminal sequence^{3,18} was different from that of *E. coli*^{1,5-7}, our further analysis shows that the two sequences are identical except that the 3' terminal adenosine in *E. coli* rRNA is replaced by UCUA_{OH} in the thermophile. Thus, the rRNA pyrimidine tract which is complementary to mRNA initiator regions appears in both 16S molecules and cannot be the basis of the different mRNA recognition patterns shown by ribosomes from the two species at 49 °C.

Although contributions to messenger recognition by other regions of 16S RNA have not been ruled out by our results, variation in one or more of the protein components seems likely to be responsible for specificity differences between *E. coli* and *B. stearotherophilus* ribosomes. In fact, reconstitution studies¹¹ which measured the capacity of hybrid ribosomes from these two species to recognise the three R17 initiator regions showed the 30S protein fraction (rather than the 16S RNA) to be the primary specificity determinant. One contributor²² is apparently protein S12, which may exert its effect by altering the association of initiation factors with the ribosome (see ref. 23 for a discussion). In addition, Isono and Isono²⁴ have shown that protein S1 is either absent from or

functionally distinct in *B. stearotherophilus* compared with *E. coli* ribosomes; they further reported that addition of *E. coli* S1 to *B. stearotherophilus* ribosomes at 39 °C allows efficient translation of the phage f2 coat and replicase cistrons²⁵. We conclude that molecular models explaining functional differences between ribosomes should not be formulated on the basis of limited sequence information at the extreme 3' termini of 16S or 18S rRNAs; both proteins and additional rRNA sequences may contribute significantly to initiation specificity.

We thank R. C. Yuan and M. Santer for valuable discussions.

Repeated helical pattern in apolipoprotein-A-I

THE binding of lipids into globules by the serum lipid-binding proteins depends on the unique structures of these proteins. Many have a high α helix content¹⁻⁴ which is enhanced by the binding of lipid, and their amino acid sequences⁵⁻⁸ suggest that the helices are often 'amphipathic' with a long hydrophobic face buried in the lipid surface^{9,10} and an exposed polar face which interacts specifically with the charged head groups of phospholipids such as lecithin. Apolipoprotein-A-I (or -Gln-I) is the larger of the two major human high density plasma lipoproteins¹¹⁻¹³, with 245 amino acids and a helix content³ of about 70% in the native complex. Physical measurements^{10,14-16} and a study of the sequence^{10,11} suggest that in several of its complexes reconstituted from phospholipids, the protein has a loosely folded structure of between 9 and 13 helices which float in the surface of a disk-shaped bilayer 5.5 nm thick and 11 nm in diameter^{17,18}, rather as logs float on water. With pure lecithin and A-I protein, each complex contains two protein and about 200 lipid molecules¹⁹. The pattern of non-polar groups in A-I protein is unusually regular, even for a helical structure, and this suggested that the sequence may have evolved by internal gene duplication²⁰ in the same way as some other long repetitive structures^{21,22}. Barker and Dayhoff²³, Fitch²⁴ and I independently found a regular 11- or 22-residue repeat pattern in it. Here I report an analysis of the repeats and discuss their structural significance.

To study the repeat pattern, the sequence was compared with itself by matching together all possible segments of a chosen length, using the comparison matrix method²⁵. There is evidently a strong pattern of repeats (Fig. 1) based on a 22-residue unit, which is itself made of two similar 11-residue halves. Initially two sets of calculations were done to explore the pattern; one with a long span of 29 amino acids to look for weak repeats extending over a long range; the other with a span of 11 to look for shorter features. These showed that the strongest repeats involve residues 120-185, where a pattern of 22 amino acids occurs three times over. Next, these three segments were aligned with one another and used as a basis for interpreting the rest of the pattern objectively. To look for the most consistent alignment a family comparison matrix was calculated, which used an average score between any part of the sequence and corresponding parts of the three aligned units (with span 11 and several sets of threshold values).

The results suggest that the protein divides into several regions: three regular repeats of 22 amino acids, residues 120-185; a fairly strong continuation of the pattern (186-240) which stops short of the C-terminal region (241-245); a strong pattern in residues 84-119, apart from one gap near Trp 112; an interrupted fragment of the main pattern (47-78); residues 1-47, which show no significant trace of the repeat, even though

Fig. 1 Comparison matrix for human apolipoprotein-A-I with span 29 and all weights of 1. Points indicate centres of 1,226 off-diagonal spans with scores ≥ 125 . In a random sequence of this composition only 1 in 1,000 or 61 out of 5,970 spans should reach this score. Thick diagonals mark centres of 78 highly significant spans with scores over 146, for each of which the frequency predicted by chance is 1 in 10^6 . Marks along axes show proline residues at positions 65, 103, 124, 146, 168, 212 and 223.

the hydrophobic groups in residues 8-33 have the distribution characteristic of an amphipathic helix.

The best alignment (Fig. 2) is reasonably certain between residues 84 and 221, but the repeat of 11 residues within the basic unit of 22 leads to ambiguities elsewhere, so that several parts of the pattern might be misplaced by 11 residues (for example, near Pro 223). In spite of some uncertainty the observed pattern clearly fits the hypothesis that the protein contains a basic unit of 22 residues, repeated eight times in all.

How significant are the repeats? The answer depends on the null hypothesis, which is assumed. The simplest criterion is to compare the distribution of comparison scores with the expected one for a random sequence of the same composition (for a span length as long as 29, it is necessary to allow for the finite sequence length of 245 residues²⁶). Table 1 shows the distributions for the matrix with span 29 and weights of 1. The number of high scores is very significantly raised in the upper range above 110. In particular, the highest observed score of 162 has a predicted frequency of 10^{-9} and would be reached in less than one random sequence out of 10^4 . The expected top score of 138 is attained in 270 spans instead of two (note that the matrix is symmetric and so each span is counted twice). The odds against such a result in a random sequence are astronomical. Objection might be made that the

Table 1 Apolipoprotein-A-I comparison scores

Score compared with:	Expected frequency	Expected number	Found number
Self			
96	0.26	15,563	16,406
110	0.033	1,973	5,344
119	4.8×10^{-3}	287	2,228
125	1.0×10^{-3}	61	1,226
138	1.9×10^{-5}	1	270
155	2.6×10^{-8}	0	44
162	1.1×10^{-9}	0	2
Myoglobin			
93	0.25	9,555	10,541
105	0.046	1,730	2,386
112	0.011	428	625
119	2.1×10^{-3}	79	90
128	1.6×10^{-4}	6	2

Span 29 and weights of 1. Scoring scheme from ref. 25.

lipoprotein sequence is clearly not random, because of its high content of amphipathic helices, and that the repeats are a natural consequence of this structural feature.

To test this contention similar comparison matrices were run for apolipoprotein-A-I against other proteins with a high helix content: apolipoprotein-C-III (Ala)⁸, human serum albumin²³, and sperm whale myoglobin²⁷ (Table 1). In each case there was some enhancement of the number of high scores in the range 110–130, but no really high scores, above 133, were found. Thus the observed repeats in apolipoprotein-A-I are much stronger than can be accounted for merely by a high content of amphipathic helix. It therefore seems most likely that residues 47–240 have evolved by gene duplication from an ancestral unit of 22 amino acids which itself is a doublet of two sets of 11. The tests also suggest that apolipoproteins A-I and C-III do not have a common ancestor, as proposed by Barker and Dayhoff²³.

The characteristic structural features of the pattern (Fig. 3) can be seen in the five most regular repeats (99–207) which are derived from a sequence of the type: (1) Gln-Lys-Leu-Ala-Pro-Leu-Ser-Asp-Glu-Leu-Arg (11); (12)-Gln-Arg-Ala-Thr-Gln-His-Leu-Glu-Ala-Leu-Arg (22) (this is not an ancestral sequence but merely a selection of the most common residues in each position). The pattern of hydrophobic residues (period 22) forms a band along one face of the helix, whereas the pattern of polar groups, with a period of 11, consists of a triangle of three negative charges bordered by three positive charges which all lie on the opposite face. The charge distribution is peculiar to this protein and occurs very consistently in the repeats. It seems well adapted to interact with a dipolar lecithin head group in the way proposed by Segrest⁹.

The nature of the repeated motif strongly suggests that the evolutionary repeat unit of 22 residues is also a structural element, which builds an amphipathic α helix with a proline at the amino end, the surface charges of which form a pair of phospholipid binding sites spaced 1.7 nm apart. Notice that three turns of α helix use 10.8 residues, so that a repeat period of 11 or 22 residues is particularly favourable in a helical structure (compare the well known seven-residue repeat in tropomyosin²¹). One notable feature of the sequence as a whole is that an unbroken helix would form a continuous hydrophobic face in long runs including residues 8–33, 44–77 and 86–240. Thus the prolines may not form sharp bends in the lipid complex, but only cause small changes of direction in a series of colinear helices of a total length approaching 30 nm. Such

Fig. 2 Amino acid sequence (one-letter code) aligned to show repeat patterns of 22 and 11 residues. Circles pick out large non-polar groups. Note three strong repeats between 120–185, a gap after Trp 112, breaks at 79–83 and 46, and absence of regular pattern in residues 1–46 and 241–245.

Fig. 3 Helix diagram of 22-residue repeat with 3.6 residues per turn. Sequence reads downwards right to left as if projected on to a sheet of paper wrapped twice round the helix axis and then unrolled. Each residue appears twice to show continuity of pattern clearly. P, Proline; ●, large hydrophobic group. Sizes are proportional to the numbers of each type in residues 99–207.

a structure could run round the circumference of the observed disk-shaped globule. On the other hand, the apoprotein itself without any lipid probably has a compact but loosely folded structure²⁸ which could form by stacking adjacent helices in anti-parallel pairs, rather as in the purple membrane protein²⁹.

Dr Fitch²⁴ has made an interesting phylogenetic analysis of the repeats and I thank him for correspondence.

matters arising

Substitution of guanine for a specific base in tRNA by extracts of Ehrlich ascites tumour cells

WE previously reported the partial purification of an enzyme from Ehrlich ascites tumour that catalysed the incorporation of GMP from GTP into specific tRNA molecules¹. The active primer tRNAs for this reaction were found from *Escherichia coli*, Ehrlich ascites tumour, sarcoma 180, and tissues of mice infected with Friend virus, but not from tissues of normal mice. Among the ten purified tRNAs of *E. coli*, only tRNA_{II}^{Leu}, tRNA_{III}^{Ser}, tRNA_I^{Tyr} and tRNA_{II}^{Tyr} were active as primers. These results suggested that, in mouse, primer RNAs are specific to tumours or tissues infected with tumour viruses. We thought that guanosine triphosphate was the actual substrate, because the reaction was neither inhibited by creatine phosphate and creatine phosphokinase, nor by inorganic phosphate, but inhibited by inorganic pyrophosphate.

More recently, however, we have found that the incorporation of radioisotope from ³H-GTP into an acid insoluble fraction was not due to GTP but due to guanine contamination in the reaction mixture. It was shown by thin-layer chromatography on an Avicel SF cellulose plate that about 6% of radioactivity was accounted by ³H-guanine. We have found that α-³²P-GTP was not incorporated in this reaction, and ¹⁴C-GTP was not incorporated. It is very likely that ³H-labelled GTP apparently decomposed to yield ³H-guanine by self-decomposition due to radiation². In fact, the enzymatic incorporation of guanine showed an absolute requirement for acceptor tRNA (Table 1), but no energy source, for example ATP, was required.

Purified *E. coli* tRNAs were tested as acceptors for guanylation by the enzyme (Table 1). tRNA_{II}^{Tyr} and tRNA^{Asp} were very active. Slightly active tRNAs, tRNA^{Asn}, tRNA^{His}, tRNA_{III}^{Ser}, tRNA_{II}^{Leu} and tRNA_{II}^{Val}, were determined with the activities of charging of the specific amino acid. tRNA^{Asn} and tRNA^{His} were not contaminated with tRNA^{Asp} or tRNA^{Tyr}, but tRNA_{III}^{Ser}, tRNA_{II}^{Leu}, and tRNA_{II}^{Val} were found to be appreciably contaminated with tRNA^{Asp} or tRNA^{Tyr}. Thus probably only tRNA^{Tyr}, tRNA^{Asp}, tRNA^{Asn}, and tRNA^{His} act as acceptors. It can be concluded that the primer activity of

tRNA_{III}^{Ser} and tRNA_{II}^{Leu} in the preceding paper¹ is due to such contaminating tRNAs. Four tRNAs that were active in guanylation contained in common the modified base Q in the first position of anticodon^{3,4}.

Table 1. Incorporation of ¹⁴C-guanine into amino acid-specific *E. coli* tRNAs

<i>E. coli</i> tRNAs (A ₂₆₀)	¹⁴ C-Gua incorporated (pmol)	
tRNA _{II} ^{Tyr}	0.006	2.0
	0.05	4.3

The enzyme was partially purified by the same procedure described by Itoh *et al.*¹. The standard reaction mixture contained in a total volume of 0.25 ml, 22 μmol of Tris-HCl, pH 8.0, 3.2 μmol of MgCl₂, 0.02 μmol of 2-mercaptoethanol, 10 nCi of ¹⁴C-guanine (55 mCi mmol⁻¹), 30 μg of enzyme protein and each of the indicated tRNAs were added. After incubation at 36 °C for 20 min, the cold 5% trichloroacetic acid-insoluble materials were collected on membrane filters, and the radioactivity of the dried filters was counted by liquid scintillation counter. *E. coli* tRNAs were supplied by Dr S. Nishimura (National Cancer Research Institute).

After tRNA_{II}^{Tyr} labelled with ¹⁴C-guanine by the enzymatic reaction was isolated and treated with RNase T₂, it was fractionated by two dimensional cellulose thin layer chromatography. The radioactive product obtained by the treatment of ¹⁴C-guanine incorporated tRNA_{II}^{Tyr} with RNase T₁ was fractionated by two-dimensional PEI (polyethylenimine)-cellulose chromatography. The results obtained from these chromatograms and acceptor activities of tRNAs suggested that the enzyme catalysed the reaction to exchange the Q base for guanine at the first position of anticodon.

Farkas and his co-workers previously reported guanylation of tRNA in rabbit reticulocytes^{6,7}. They showed that the guanylated tRNA of rabbit reticulocytes were tRNA^{His} and tRNA^{Asn} (ref. 8). Okada *et al.* recently studied this guanylation reaction in order to identify the exact

position of guanylation and the guanylated species of tRNA. They showed that the Q base in the first position of the anticodon of *E. coli* tRNAs (tRNA^{Tyr}, tRNA^{Asp}, tRNA^{Asn}, tRNA^{His}) was replaced by guanine by the guanylation enzyme from rabbit reticulocytes⁹. It was found that tRNAs isolated from Ehrlich ascites tumour and AH7974 rat ascites hepatoma were active as acceptor for guanylation with the enzyme from Ehrlich ascites tumour, but normal mouse and rat liver tRNAs were not active (ref. 1 and unpublished data). Kasai *et al.* reported that the Q* (a derivative of Q) content of liver tRNA of AH7974 rat ascites hepatoma was twofold greater than that of normal rat¹⁰. One of the major factor of a difference of guanylation activity among these tRNAs is probably the modification of nucleoside such as Q and Q*. Furthermore, a specific structure or sequence common to these tRNAs may be recognised by the enzyme. It will be interesting to examine the structure of tRNAs from tumour cells concerning the guanylation activity.

This work was supported in part by grants from the Ministry of Education, Science and Culture, of Japan, the Waksman Foundation of Japan Inc., the Mitsubishi Foundation, and Keio University School of Medicine Research-aid Fund. We thank Drs S. Nishimura and F. Harada of National Cancer Center Research Institute for help in product analysis and valuable suggestions.

Amino acids in fossil woods

THE significance of the amino acid racemisation date for fossil wood from the Kalambo Falls Prehistoric Site, Zambia, recently reported by Lee, Bada and Peterson¹ requires clarification. The specimen used for ¹⁴C calibration (UCLA-1857), referred to throughout as 'Sangoan wood', is noted on Table 1 of ref. 1 as being 'Kalambo Falls, Site A, River Face (1959) Pit 3, No. 49 (9 ft 9 inch)'.

Because of apparent stratigraphic correlations when this specimen was excavated, it was entered in the field catalogue as being 'Sangoan' in context; this was the notation which was on the sample when it was supplied for racemisation dating. The stratigraphy of the Site A River Face was re-examined in 1963, however, and the section drawing², and field notes, show that this specimen came from a bed in the uppermost White Sands and Dark Clays, from which aggregates including diagnostic Acheulian artefacts were recovered nearby. (The 9 ft 9 inch refers to a field datum; the depth below the published trench datum is 13 ft 9 inch).

That the analyses indicate that the Site A specimen is younger than that from Site B is in agreement with the postulated stratigraphic relationships^{3,4} and palynological evidence⁵. Older ¹⁴C dates have been obtained on wood in equivalent, Site A contexts: >49,000 (GrN 3211); >52,000 (GrN 4228); 61,700 ± 1,300 (GrN 4896) = >60,000 (ref. 5). These would give an older racemisation date for the Site B wood.

Thus, both the analysed specimens from Kalambo Falls have Acheulian cultural associations, and the date of >110,000 for Site B has little bearing on the 'Acheulian-Sangoan transition.' It refers to the Moola Phase of the Bwalya Industry, not to the youngest Acheulian⁶. It is vital that specimens within the ¹⁴C dating range be obtained for calibration, in order to derive finite dates for both of these older woods.

Ductile shear zones and basal aureoles in ophiolite complexes

ATKINSON¹ has recently attributed ductile shear zones in the Bay of Islands ophiolites of Western Newfoundland to the 'transportation and emplacement of oceanic crust and mantle on to a continental margin'. This may be so for some such zones, although the well-exposed basal thrust of the ophiolite-bearing White Hills slice in northern Newfoundland is not associated with either the ductile style of deformation or the 'low greenschist grade' assemblages that Atkinson describes. Moreover, in the Bay of Islands complex there are well defined ductile shears in both the interbanded transition zone between the harzburgites and the gabbros and in the lower parts of the gabbros themselves, that seem to be related to processes near accreting plate margins^{2,3}.

These are best seen in the Lewis Hills, where a wide variety of dunites, harzburgites and gabbros are intensely mylonitised (though rarely to greenschist facies) in zones from several metres wide down to a few centimetres. These zones, many of which are axial-planar to tight folds, are cut by much less deformed dykes and sheets of hornblende gabbro, which seem to have been derived from a tholeiitic parent. Other clear evidence of the overlapping in time of igneous and deformation events is provided by the presence of rotated inclusions of foliated gabbro in relatively massive wehrlite.

It seems then that the ophiolites were undergoing deformation in narrow zones of high strain before they were carried with the spreading ocean floor far from their place of origin at an oceanic ridge or possibly at a transform. It is unlikely however, that the basal aureoles formed in the same environment by the 'lateral flowage of oceanic crust and upper mantle' as Atkinson speculates. Most of the protoliths for these aureoles were distal continental

margin sediments and associated volcanics^{4,5} which were overridden by the ophiolites during their advance onto the continental margin.

ATKINSON REPLIES—Berger and Jamieson's comments on 'ductile shear zones' in the Bay of Islands ophiolites refer to high-grade structures and assemblages related, in some way, to the formation of Late Cambrian lithosphere at an ocean ridge and to its subsequent lateral flowage during sea floor spreading. I am most familiar with these previously documented structures and agree with this interpretation of their origin.

Ocean floor spreading, however, does not emplace ophiolite sheets on to continental margins. My letter to *Nature*¹ dealt specifically with younger, lower-grade minor structures formed during a late Arenig-Llanvirnian period of ocean basin closure. Crustal shortening was accommodated by telescoping the North American continental margin along major thrust faults. These were singularly responsible for the transportation and emplacement of the Bay of Islands ophiolites on to the continental margin. Field observations of the faults show that they are sharp, clear-cutting surfaces—certainly in no way 'ductile' zones themselves. My reference to ductile deformation zones (DDZ) is in regard to minor structures found within the body of the Bay of Islands ophiolite sheet. These DDZ cut across and retrograde the gabbros, harzburgites, dunites, and 'aureole' rocks, as well as all those structures mentioned by Berger and Jamieson (including the mylonites of higher-grade DDZ).

Clearly, the observations of Berger and Jamieson and previous authors on relatively high-grade DDZ related to ridge and spreading processes are not being challenged here. The observations I have made concern a distinctly later event—one that was responsible for ophiolite transportation onto the continental margin some 40 Myr later.

reviews

Dispelling fears over pesticides

F. Moriarty

Pesticides and Human Welfare. Edited by D. L. Gunn and J. G. R. Stevens. Pp. 278. (Oxford University: Oxford and London, 1977.) Hardback £5; paperback £1.75.

THERE has been a great deal written and said about the alleged disadvantages and dangers of pesticides. This book has been produced in response to this publicity, and is sponsored by seven chemical companies from western Europe, including ICI and Shell from England. The book is intended for laymen and non-specialists, and so discusses, in a lengthy appendix, the meaning of some common technical terms, types of pesticides, their formulation and biological activity. The main text contains three parts, with a total of twenty chapters, each intended to be scientifically accurate, intelligible and authoritative.

There are four chapters in part one. The first three, on the world's food supply (W. R. Furtick), population growth (R. H. Gray), and vector-borne diseases (G. Davidson), introduce the problems that pesticides can help to solve. They combine to illustrate vividly the differences between the industrialised and the developing countries of the world. Data are provided for past and expected future increases in population and food production. It is estimated, for example, that pests consume about 30% of the potential food production in the developing countries, but they use only 10% of the world's pesticides, mainly for public health and exported crops. The developing countries have higher rates of population increase, and, just to maintain present standards, their food production will probably need to almost double during the next twenty-five years. The important point is made several times that methods of food production, medical services and birth rates cannot be considered in isolation, but are all components of a society's culture. Thus, the effective use of pesticides in food production implies a relatively sophisticated agricultural industry. The fourth chapter, by D. J. Ansell, explains some of the financial difficulties in increasing food production in the developing countries.

The second part, with ten chapters, provides examples of how pesticides improve crop yields, animal health and

food storage. The criterion by which pesticides are judged is their cost against the value of the increment in yield. G. Schumann suggests, particularly from German experience, that farmers get a return of between 1:3 and 1:9 for pesticides, going in exceptional cases as high as 1:100. Several other chapters comment, for specific crops, on the lack of precise figures: the introduction to the chapter on tropical cash crops discusses some of the reasons for this, and concludes that in general when pesticides are used their benefits are so obvious that detailed data are unnecessary. Such calculations, when possible, are based of course on a micro-economic analysis. D. E. Jacobs indicates that realistic cost-benefit analyses for an entire community need computer-aided models. J. P. Hudson touches on another aspect of the same problem when he explains that for commercial orchards, once the current standard spraying regimes have been used, it would be disastrous to stop spraying.

The final part, in six chapters, discusses complications of, and alternatives to, pesticides. It is clear that pest resistance to pesticides (J. R. Busvine) is a continuing major worry. The late J. M. Barnes presents a reassuring account of the hazards to people; the major risk comes from human carelessness, not from unexpected toxicity. I am not completely convinced that animals will always be adequate indicators of possible chronic toxic effects in man (p188), but that is a minor quibble. K. Mellanby discusses the "balance of nature" and makes the point that one can never prove that all hazards from pesticides are known. Nevertheless, he sees little cause for

alarm on this score, although I doubt whether we have too much evidence either way for some of the developing countries. D. P. Jones discusses the topical issue of energy costs and gains from pesticides. R. F. Glasser describes some of the controls imposed by governments on the development and use of pesticides, and suggests, as do several other authors, that the increasing costs of research are reducing the amount of research for new pesticides. It would have been interesting to have some comments on the fact that it is becoming more difficult to discover new potential pesticides at the primary screening stage. The final chapter, by D. L. Gunn, discusses alternatives to pesticides and concludes that pesticides will remain of major importance for the foreseeable future.

This book succeeds in its aims. It is clearly written, the few minor misprints causing no problems except for conventional (*sic*) on p212; most of the chapters read convincingly; and the book should inform and stimulate its intended audience. There are some omissions; for example, there are few if any data on quantities of pesticides manufactured and used, and few references to forestry or to herbicides in waterways. The major unanswered query was, where are we going? Clearly, in the short term, we will continue to need and use pesticides. In the long term, if pesticides merely enable us to keep one jump ahead of population increase, for how long will we be able to maintain that state of affairs? □

Dynamics of atomic liquids

Atomic Dynamics in Liquids. By N. H. March and M. P. Tosi. Pp. 330. (Macmillan: London, 1976.) £25.

IT is difficult to decide for whom this book is intended. The level of discussion is high and the range covered is very wide. As may be expected the longest chapter is on charged fluids (plasmas, liquid metals and molten salts), a field to which the authors have

made important contributions. Apart from the conventional general discussion of the structure and dynamics of pure atomic liquids and binary liquid mixtures there are short specialised chapters on the helium liquids, the liquid surface and on critical phenomena. Few topics are discussed or explained in any detail, and a considerable expertise in theoretical physics is a prerequisite. Consequently this book cannot be recommended to the beginner. On the other hand it will not be very exciting for the expert, except as a reference book.

The material is not well organised and the

text does not read smoothly—quite apart from many errors of English and poor proof-reading. There is excessive direct quotation of formulae from specialised papers with inadequate indication of the physical assumptions involved. It is clearly difficult to decide in what detail to deal with this wide range of topics in a small book, but the authors have not found a happy solution. Many parts of the book, and its general arrangement, give the impression of very condensed notes for lecture courses. The lecture courses themselves were pro-

bably very good but they are not given here.

In view of the well established reputation of the authors and the significant contributions they have made to the theory of liquids it is to be regretted that they have not produced a book which does them justice.

This will be a useful reference work for experts and it is perhaps in anticipation of this that the price has been set very high.

J. G. Powles

J. G. Powles is Professor of Physics at the University of Kent, Canterbury, UK.

Remote sensing

Introduction to Environmental Remote Sensing. By E. C. Barrett and L. F. Curtis. Pp. ix + 336. (Chapman and Hall: London; Halsted/Wiley: New York, 1976.) £5.95.

THE authors' aim "has been to meet the needs of many students, administrators and scientists for an account of remote sensing which is essentially basic, explanatory and broad in its coverage", illustrating applications as well as techniques. There is certainly a need for such a book to be read, particularly by the administrators and scientists who control in various ways the support (or lack of support) and encouragement for the development of remote sensing and its applications. Does this book satisfy its declared aims?

A range of publications is now available on the subject of remote sensing, from popular accounts, through textbooks and books of collected papers to the *Manual of Remote Sensing* recently published (American Society of Photogrammetry: Falls Church, 1975) in two large volumes. The authors of the book now under review have re-written and edited some of these earlier accounts.

Just over half of the book is concerned with a "selective and illustrative" treatment of applications, covering a range from global climatology to urban studies, and this is perhaps the most useful half of the book for its stated purpose. The atmospheric aspects of the environment receive more attention in this book than in some others, which is not surprising in view of the authorship.

The first half of the book is concerned with the techniques rather than with the applications of remote sensing. The description of the physical basis of remote sensing and the radiation characteristics of natural phenomena reach about the intended level. The chapters on the techniques—that is, the sensors and data processing—are not so satisfactory. Too much previous knowledge is required for this to be included in a basic textbook, and an attempt has

been made to convey too much and too complex information in a small number of words. As one example, in nearly three pages on photographic processing the terms γ , MTF, film stability and granularity, chloride, chlorobromide and bromide papers, and sequential colour printing are introduced among many other topics.

Illustrations and references (including eight pages of colour figures), are both good and plentiful, except that quoted sources of illustrations are frequently not referenced.

It is unfortunate that the text contains enough misprints to be irritating. Occasionally these are factual: for example, the first introduction of ERTS 1 MSS imagery (Plate 3.3, p40) lists the spectral bands wrongly, although it must be said that they are frequently described correctly later in the book.

Overall, this reviewer gives a 'two cheers' reaction—good on applications and illustrations, and reasonably priced in these inflationary days, but barely suitable as a basic textbook on remote sensing techniques.

J. R. Hardy

J. R. Hardy is Senior Lecturer in Geography at the University of Reading, UK.

Human hormones in health and disease

Hormones in Human Blood: Detection and Assay. Edited by H. N. Antoniades. Pp. xvii + 810. (Harvard University: Cambridge, Massachusetts and London, 1976.) £37.10.

THE editor of this multi-author book, Dr H. N. Antoniades, quotes with approval in his Introduction the 1960 statement of Dr G. W. Thorn in his foreword to *Hormones in Human Plasma* that it would be impossible "ever again, to contain within one single volume all information pertaining to this important subject". The dust cover states that *Hormones in Human Blood* "will be an indispensable companion to laboratory workers engaged in clinical and research efforts to measure and understand the role

of human hormones in health and disease". With the book priced at £37.10 this claim merits close examination.

This volume contains 46 chapters contributed by 69 authors covering some 800 pages. The three initial chapters are concerned with plasma proteins and plasma fractionation techniques. The next eight chapters deal with basic aspects of radioimmunoassay methodology. The subsequent and largest section of the book (30 chapters) covers polypeptide hormones and the last section (five chapters), non-polypeptide hormones. A fairly rapid poll of the references quoted suggests that most chapters are completely up-to-date, with 1973 references and 1974 publications of the chapter authors; some go into 1975 and the chapter on growth hormone notably contains 1976 (in press) references which is remarkable as this is the publication year of the book. Does one congratulate the latter authors or identify them as the tardiest contributors?

If it is impossible to be complete in this area how far short of completeness does the book fall? Inevitably it must be in the most rapidly moving new areas rather than in new aspects of existing hormones. For example, of the gastrointestinal hormones only gastrin and glucagon-like substances are considered. This omission is perhaps made more disappointing by the imbalance of the material included. Thus the coverage is considerably affected by the editor's particular interest in protein fractionation and insulin. There are five chapters on insulin immunoassay and five chapters on insulin bioassay. In addition some of this information is also covered in the general chapters on radioimmunoassay methods. One feels, therefore, that a more satisfactory endocrine cover could have been achieved without expanding the book by pruning some of this dated material.

Nevertheless the breadth of coverage provided means that it is impossible for a single reviewer to give an authoritative general opinion of the quality of the contents. Most of the authors are very well established and actively working in their subjects, and therefore their contributions must be very valuable. Inevitably, in looking in detail at the areas with which one is most familiar, one finds defects. For example, must laboratory workers accept the dogmatic statement that the pre-precipitation double antibody method "produces a less sensitive assay than post-precipitation methods", for which the only justification cited is a previous undocumented assertion of the same nature?

One cannot help feeling that the modern laboratory worker in this rapidly moving area will prefer to consult the original literature for most of the methods but will be glad if somebody not too far away has found the money to buy the book.

C. N. Hales

C. N. Hales is Professor of Medical Biochemistry at the Welsh National School of Medicine, Cardiff.

Super Proton Synchrotron project

Europe's Giant Accelerator: The Story of the CERN 400 GeV Super Proton Synchrotron. By Maurice Goldsmith and Edwin Shaw. Pp. 288. (Taylor and Francis: London, 1977.) £13.

In telling the tale of the Super Proton Synchrotron (SPS) project, Maurice Goldsmith and Edwin Shaw have produced a book that is both fascinating and frustrating. Although it is explicitly stated that the views and comments presented are those of the authors and not the official opinion of the European Organisation for Nuclear Research (CERN), the authors do not often stray from the party line, and the text tends to glorify CERN and praise the success of the SPS. And why not—it is a story to be proud of.

Beginning with a brief and rather high-minded justification for high energy accelerators the authors move straight into the political wranglings that continued for so many years before the SPS project was accepted and funded. A detailed description of the birth-throes is given but its conception is handled more discretely. It will be difficult for an uncommitted reader to become emotionally involved as the political and scientific justification for the SPS is inadequately presented. The reader needs to be emotionally involved to appreciate the detailed description of the implementation of the project which is presented in the rest of the book.

The discussion of the fight for acceptance of the SPS project is fascinating. The brevity of the discussion is frustrating. After rather full-some praise of the CERN convention—the rules by which CERN operates—it comes as a shock that it did not seem to work too well in the case of the SPS. More comment on this would have been welcome, as would be additional discussion of the roles of the various member states during the negotiations. One gets the impression that only a small part of the story has been told—enough to whet the appetite but insufficient to give full satisfaction.

Turning to the building of the machine itself, the authors describe the process in great detail in separate chapters dealing with individual aspects of the problem: surveying, magnets, power and water supplies, radio-frequency acceleration, and so on—topics beloved by engineers and belittled by everyone else, but presented here in an exciting style. Aspects often taken for granted are revealed as complex technical problems and their solution is surprisingly interesting, not

least because of the clear way in which they are presented.

Apt portraits are given of most of the key personnel in the project—a device which adds a great deal of interest to the technological descriptions but, even so, in places far too much technical detail is included and the story becomes difficult to follow. In general, however, there is a good blend of personal interest, technical detail, explanation and discussion of management techniques, which makes a very readable story.

Although the text is fascinating, the layout of the book is frustrating. Pictures are liberally sprinkled throughout; most are of interest but others are fatuous, and the text is fitted into the remaining space after huge margins have been accommodated. If a picture

is encountered, on turning a page one has to search frantically for the text; often there isn't any. Even when there are no pictures the text does not begin until nearly a quarter of the way down the page.

It would have been preferable to expand the scope of the book to put the SPS project into context and explain more fully the motivations and use to which it will be put. This could have been done without increase of the (already high) cost, at the expense of reducing the space taken up by pictures.

This book is one which can usefully be read even though it is produced as if it were a glossy handout for a publicity department. **Stuart Sharrock**

Stuart Sharrock is Physical Sciences Editor of Nature.

Organic reaction mechanisms

Reaction Mechanisms in Organic Chemistry. By Florin Badea. Pp. 701. (Abacus: Tunbridge Wells, Kent, UK, 1977.) £18.85.

THE investigation of organic reaction mechanisms by the application of kinetic measurements originated with Lapworth's work on the halogenation of acetone, at the beginning of the present century. It was not until much later, after 1930, and especially through Ingold's work on substitution reactions, that mechanistic studies became accepted as the cornerstone of the scientific basis of modern organic chemistry. Almost any recent textbook of organic chemistry, even at an elementary level, reflects this view. Several more specialised treatises, including the famous ones by Ingold and Hammett, have given more detailed analyses of the problems of reaction mechanisms in relation to the structure of organic compounds. The work now under review is a recent addition to the literature in the second category. Its author is Professor of Organic Chemistry at the Polytechnical Institute, Bucharest, Romania, and we learn that his research experience included a period in Donald Cram's laboratory at UCLA. The book is well translated (by the author, with help) into readable, though not altogether faultless, English.

The text starts with an introduction to group theory, an account of the Hückel molecular orbital (HMO) method, some rudimentary thermodynamics and statistical mechanics, a statement of the principles of chemical kinetics, and a brief survey of reaction intermediates. These sections are

followed by a detailed treatment of mechanisms of a large number of selected reactions, beginning with aliphatic substitution and ending with cycloadditions. The level of the treatment is intended for postgraduates and advanced undergraduates.

In its 700 crowded pages the book manages to include a vast amount of material and many references. Much of the information is of recent date, and it is not surprising that frequently the aptness of its selection is at least debatable. Clearly, in such an enormous undertaking, there are also bound to be errors of fact or interpretation. Some of these are excusable and could prove a challenge to a good student. The author does not generally attempt unconventional interpretations or to resolve conflicting views. He is not afraid to show his limitations and to leave the reader to develop his own critical faculty by sifting the arguments presented.

Probably the least satisfactory aspect of the book is the absence of any coherent attempt to explain the current methodology of the elucidation of reaction mechanisms. This is not a text from which a student could gain a satisfactory understanding of the application of kinetic methods and become aware of its pitfalls, for example. The treatment of topics such as the role of pre-equilibria, the stationary-state hypothesis, kinetic salt effects, or kinetic isotope effects is inadequate and sometimes seriously in error.

Nevertheless, the book is quite good in parts but, as better introductions to the subject are available in the English language, it is unlikely to be widely adopted.

V. Gold

V. Gold is Professor of Chemistry at King's College, University of London, UK.

Dynamics of fish populations

Fish Population Dynamics. Edited by J. A. Gulland. Pp. xi + 372. (Wiley-Interscience: London and New York, 1977.) £13.50; \$25.

THIS book describes how the dynamics of fish populations can be analysed in terms of the factors affecting their rate of growth, mortality and reproduction, with particular emphasis on the effects of fishing. There are sixteen contributors to the book, including the editor, and many of them have a long-standing international reputation in this field, so much so, that the chapters by Ricker, Gulland, Cushing, Regier, Larkin and Allen, and Chapman are bound to guarantee the book the success it well deserves. It is intended primarily for those already having some interest in fishery science, and for graduates and final-year undergraduates in biology and related subjects. Its form of presentation and style will make it a very 'usable' reference for fishery science undergraduates.

The book has been arranged in three parts. In the first chapter, Ricker describes the historical development of the subject and includes the quantitative methods, of increasing reliability, for describing the direct effects of fishing on stocks of fish and for predicting the catches expected to result from changes in the intensity of fishing or in the sizes of fish caught.

The next section describes some of the particular lines of investigation and methods used in more detail. Because direct observation of fishing in the oceans is difficult and expensive if carried out by special research vessels, scientists have for long depended very much on information from the commercial fisheries; Williams describes the practical problems met in collecting this data. This is a particularly valuable chapter for undergraduates and recent graduates in making them aware of the problems facing the fisheries scientist in obtaining reliable data.

The main lines of analysis as used at present, are reviewed by Gulland, whereas further lines of advance are explored by Rothschild (concerning the concepts of fishing effort and fishing mortality), by Cushing (the problem of the relation between adult stocks and the number of young produced) and by Regier (the position of the fish stock in the whole ecosystem).

The third part of the book looks at how the ideas described earlier have worked out in practice when applied to actual populations. Fish population dynamics grew up in the North Atlantic and North Pacific and much of the work was done on three fish—cod, plaice and the five species of Pacific salmon. The present state of understanding of these species is reviewed by Garrod, Bannister and Larkin, respectively. Population studies and the application of these studies to practical problems, are now worldwide. Murphy looks

at the clupeoids, representatives of which are found in most parts of the world, and Rothschild and Suda look at the larger tuna species, most of which are found in all the warmer oceans. The studies reveal how many of the ideas developed in relations to a few fish in northern temperate areas have been usefully applied to very different areas and to very different fish, but Holden shows how some basic differences in the biology of elasmobranchs require some important changes in approach. Finally, Allen and Chapman examine some aspects of the dynamics of whale stocks and in so doing give us a very useful history of whaling.

For those with little understanding of statistics this is not a book to shy away from, as it is most readable and easily understood. It is also not without its lighter moments, as when Gulland (p70), when referring to the difficulty of making direct observations on fish at sea in mid-winter, states that it "involves a large, seaworthy ship costing hundreds of pounds to run. Most fishery research laboratories have one

or more specially equipped research vessels to carry out this sea work, but their high running costs and the need to justify their even higher capital costs often cause them to hang like gold-plated albatrosses round the necks of the directors of the laboratories concerned."

In addition, the political aspects of fisheries appear from time to time, as when Larkin (p183) refers to the fact that there is no international agreement that excludes participation of all-comers in the harvesting of salmon beyond narrow coastal limits and, as he says, "at present prices for salmon, it seems only a matter of time before someone decides to test the political wind."

This is a relatively expensive book but is one which the budding fisheries scientist should not be without. **Derek Mills**

Derek Mills is Lecturer in Ecology and Fisheries Management in the Department of Forestry and Natural Resources at the University of Edinburgh, UK.

Continental drift

Continents in Motion: The New Earth Debate. By Walter Sullivan. Pp. xiv + 399 + 29 plates. (Macmillan: London and Basingstoke, 1977; McGraw-Hill: New York, 1974.) £6.95.

THIS book is aimed at the general intellectual, non-specialist reader and is undoubtedly the best book on continental drift which has yet appeared for this type of market, although its numerous anecdotes and overview makes it interesting reading even for the specialist. It was originally published in the United States in 1974 and, although it is regrettable that it has not been up-dated, the information it contained at that time was so up-to-date that subsequent data have only extended and modified certain concepts. This new publication is therefore only slightly dated.

It is a large well produced book and contains 29 colour photographs, although some of these could have been dispensed with and further black-and-white diagrams inserted. It is written, as would be expected by the Science Editor of the *New York Times*, in the best journalistic tradition—with an easy style, full of human as well as scientific interest, yet avoiding the slickness and doomwatch aspects which often spoil such books. The drawback for a non-American reader is the emphasis on American findings: most examples are taken from America or American authors, although the British contributions are amply acknowledged. Nevertheless, Arthur Holmes

still only gets a few lines, whereas the Velikovsky farce receives almost a full chapter.

There are hardly any factual errors and most do not really matter for the audience at which it is aimed, although diagrams of the *expected* magnetic anomaly patterns in the western Mediterranean should not be portrayed as the actual pattern, even schematically.

I was more disappointed that Sullivan had not really contributed himself, although this is understandable as he has mainly been a bystander. Throughout, however, there was a sneaking feeling that he has already thought of, but not voiced, the questions which the specialists should be asking themselves, but which have not yet been recognised as the real problems.

The poorest coverage is on mechanisms as the concentration is very much on plumes, with brief consideration of the possibility of shallow convection, but virtually no regard to the probable dominant factor, large scale mantle-wide convection; but this may merely reflect the reviewer's prejudices! Surprisingly, the metal-ores, other than those of the seafloor, receive little attention, although petroleum and particularly geothermal energy resources are covered. But to ask for more is really a compliment to what has been included.

The book can be unreservedly recommended to the general reader, and even specialists would find £6.95 could provide them with numerous insights and amusement, even if they learn few new facts. **D. H. Tarling**

D. H. Tarling is Senior Lecturer in the Department of Geophysics and Planetary Physics at the University of Newcastle upon Tyne, UK.

newly on the market

These descriptions are prepared by the staff of *Nature* on the basis of material provided by manufacturers. The Reader Enquiry Card faces the inside front cover.

Plasma Emission Spectrometer. Technation. The Spectraspan IV, a single element plasma emission spectrometer can perform quantitative and qualitative analyses of trace concentrations including refractories and some non-metals. It has a high sensitivity even in the presence of complex matrix solutions with solids contents as high as 20%. The high intensity excitation source is a d.c. argon plasma which operates at low power but produces temperatures as high as 10,000 K. An integral microprocessor increases efficiency and allows routine performance checks.

Circle No. 42 on Reader Enquiry Card

Radiation dosimeter in SI units. Dosimeter. A radiation dosimeter in SI units, the Model 883 is calibrated 0–129 $\mu\text{Ci kg}^{-1}$ and 0–500 mR.

Circle No. 43 on Reader Enquiry Card

Graphite furnace. Perkin-Elmer. The HGA-2100 graphite furnace, a flameless sampling system is for use with atomic absorption spectrophotometers has the new gas stop and mini gas flow system which controls sensitivity during atomisation. This graphite furnace can determine most metallic elements with detection limits up to 1,000 times better than those obtained with conventional burner systems. Solution volumes as small as a few tenths of a microlitre can be analysed as easily as larger samples of up to 100 μl required when measuring extremely low concentrations or non-homogeneous materials. Addition of a temperature ramp accessory provides a convenient means of automatically increasing temperature during all three phases of operation, dry, char and atomise. The HGA-2100 can also analyse many solid samples directly—materials that have been successfully analysed without prior dissolution include plant tissue, polymers, finger nails and paper products. The determination of metallic elements in difficult matrices is also simplified by the design of the gas flow and sample introduction systems. Lead can easily be determined at low levels in 6 N solution of sulphuric acid.

UV-Vis spectrophotometer. Perkin-Elmer. The dual wavelength, double beam, UV-Vis Spectrophotometer, Model 556, is suited for applications involving turbid samples, mixture analysis and other biochemical and industrial applications. Two separate diffraction grating monochromators, with independent selection of wavelength, produce the sample and reference beams which pass along identical paths through the sample cell. To record the spectrum of a turbid sample where no reference solution exists, one monochromator can be fixed and the other set to scan. Alternatively, the two monochromators can be fixed a few nanometers apart and both scanned together to record the first derivative of a spectrum. Double beam operation is with both sample and reference beams taken from one monochromator. Regular difference spectra can be recorded with a high performance level.

Philips new PW 1720 table-top X-ray generator equipped with Debye-Scherrer, Universal flat plate and Guinier cameras.

Table-top generator. Philips. The PW 1720 top measures 750×700 mm and with standard Philips tube shield, will easily accommodate single crystal goniometers and Debye-Scherrer, Guinier or Universal flat plate cameras. A vertical goniometer for diffractometry can also be fitted. The height of the generator top is 380 mm, enabling it to be placed on a table and provide an ideal working height for camera alignment. The basic generator is full wave rectified, with rated power consumption of 2,500 VA max., and has full tube current stabilisation, continuously adjustable between 5 and 60 mA. Current stability is <0.3% per % mains voltage variation of $\pm 10\%$, with drift <0.2% per $^{\circ}\text{C}$ at ambient temperature.

Circle No. 46 on Reader Enquiry Card

Thermal imaging camera. Marconi-Elliott. The pyro-electric camera has a special Vidicon camera tube which responds only to heat radiated from a subject with no contribution whatever from light in the visible spectrum. The camera gives an output which is completely compatible with standard 625 line TV equipment. This, and its portability, has been demonstrated by its use as a 'roving' camera. Hitherto thermal imaging cameras involved highly complex and expensive forward looking infrared (FLIR) systems, based on the use of a large matrix of discrete heat sensing elements, in conjunction with a very high speed mechanical scanning system. Their cost greatly limited the application of thermal imaging techniques. The Vidicon camera, whose construction and operation is similar in principle to that of a conventional TV camera, can extend the technique to a variety of industrial, medical and even domestic uses. Working with virtually any TV monitor the camera can show pictures which bear a remarkable resemblance to those taken by cameras using visible light using only the pattern of thermal energy produced by the object. Thus 'hot spots' in rotating machinery, including for example, vehicle tyres, can be readily located as can thermal stress in power cables and soil patterns in aerial surveys. For medicine a camera of this kind could have application in thermography for the diagnosis of tumours. For surveillance, an intruder can be detected even in total darkness. Its use in defence equipment is also significant since, by not requiring to irradiate the object observed with infrared energy, the presence of the observer cannot be detected.

Circle No. 47 on Reader Enquiry Card

Programmable multiple reagent dispenser. Dynatech. The Dynadrop delivers up to 12 individual reagents to a Microtiter plate in quantities from 10 to 200 μl within an overall accuracy of $\pm 2\%$. Individual reagents are contained in a rack of test tubes which in turn is located in a low pressure reservoir. An integral pump provides filtered supply air at up to a maximum of 5 lbs inch^{-2} . The reservoir, connecting tubes and dispense manifold are all autoclavable.

Circle No. 48 on Reader Enquiry Card

Digital radiometer. Ultra-Violet Products. The J-260 digital radiometer measures UV intensities rapidly and automatically. Digital readout in radiometric units is within a broad dynamic range of $1 \mu\text{W cm}^{-2}$ to 199.9 mW cm^{-2} with accuracy, traceable to NBS, $\pm 1.0\%$ of full scale. High sensitivity for measuring low level irradiance is to the order of ± 1 digit. The radiometer is available with cosine-corrected sensors for measuring at 254, 297 or 365 nm. It is fully portable, uses alkaline or rechargeable NiCd batteries and is supplied complete with choice of sensor, batteries and recharger.

Circle No. 49 on Reader Enquiry Card

Navigational echosounder. Marconi. The Seahorse features possibly the largest chart to be found on any known navigational echosounder, an integral readout, automatic range change facilities and a depth alert. Optional extras are a large size remote digital readout and a large analogue meter-type display. Seahorse provides two depth ranges 0–100 m and 0–1,000 m, and a depth alert system.

Circle No. 50 on Reader Enquiry Card

Portable infrared gas analyser. Wilks Scientific. The Miran 104 portable gas analyser is a light-weight 14.5 m variable path length gas cell which, when allied to the Miran spectrometer, produces a high sensitivity and specificity analyser.

a, Debye-Scherrer cameras. Camera correctly installed—safety arm activates microswitch to open beam shutter.
b, Part of camera (exit tube) removed—safety arm de-activates microswitch to close beam shutter.

Debye-Scherrer Cameras. Philips. The PW 1024/30 and PW 1026/30 cameras can be used with any Philips tube tower provided with an external safety microswitch, and use the standard diameters of 114.83 mm and 57.54 mm respectively. An important safety feature is a counter-balanced arm which can only activate the safety microswitch—to open the tube tower shutter—when the camera is correctly installed. If the camera, or any part of it, is removed the arm releases the microswitch and the tube tower shutter immediately blanks-off the X-ray beam. The arm also prevents the inadvertent use of an entry collimator in place of the correct exit tube. Exit tubes are now of one-piece construction so that removal of the lead safety glass is impossible.

The camera body and pedestal are formed as a single integrated unit so that alignment relative to the tube tower exit is automatically correct. Accuracy is improved because the collimator and exit tube are always in correct alignment.

Circle No. 53 on Reader Enquiry Card

Portable noise monitor. Radiatron Instruments. A self-contained portable noise monitor, designed to calculate and print-out community noise levels the Model 614 will print out a wide variety of noise data. The instrument can be equipped to provide a threshold-controller single event printout (such as a flyover) including start and stop time and maximum noise level.

Circle No. 54 on Reader Enquiry Card

Mass spectrometer. Varian MAT. The MAT 260 spectrometer system is intended for automatic precision analysis of isotope ratios in solids (U, Pu, Rb, Sr, Pb and others). A programmable desk top calculator HP 9825 A is an integral component of the mass spectrometer system, optimising the ion source, controlling analysis procedures as well as evaluating and listing results. Twelve masses can be preselected for each measuring cycle, the user having the choice of manual 'one-off' measurements and fully automatic analyses of up to 13 samples mounted in a sample magazine. The exceptional performance of the MAT 260 is due to the high efficiency of a totally new ion source employing two einzel lenses, and the near 100% transmission of the newly developed stigmatic focusing analyser, the resolving power of which corresponds to that of a conventional 46 cm radius system. System sensitivity is better than one ion per 1,000 atoms of uranium. Internal reproducibility is better than 7×10^{-5} . Optimum vacuum conditions are generated by a turbo-molecular pump, two getter ion pumps and a cryo pump. The pumping system is almost maintenance-free and requires no cooling water connection. Devices for sample handling and preparation are included in the system.

Circle No. 55 on Reader Enquiry Card

Varian MAT 260 Spectrometer system

Conductivity meter. Pye Unicam. The PW9505 has a choice of 10 standard measuring ranges from 0 to $3 \mu\text{S cm}^{-1}$ up to 0–100 mS cm^{-1} . A single specially developed plastic conductivity cell PW9514/60 covers all these ranges. The large 0.5% class meter minimises reading errors and gives high accuracy and facilities are provided for conductimetric titrations, reference measurements and ordinary resistance measurements. Reference temperature is normally 20°C but it can be extended to 25°C with a minor modification. Manual or automatic temperature compensation is provided. The manual mode covers the range 0–50 $^\circ\text{C}$. The automatic mode, using the Pt100/1 resistance thermometer or reference cell, covers the range 0–100 $^\circ\text{C}$.

Recombinant DNA: local or federal regulation?

AFTER raging through college campuses and state and local government offices throughout the United States, the debate over the risks and benefits associated with recombinant DNA experiments has now reached a critical juncture in the US Congress. In the next few weeks, committees in both the House of Representatives and the Senate are expected to approve their own versions of legislation to regulate recombinant DNA experiments. Although substantial differences of opinion between the House and Senate committees are emerging on key aspects of the legislation, one point in particular has become the focus of a major lobbying effort by members of the scientific community: the extent to which federal regulations governing recombinant DNA activities should over-ride controls adopted by state and local governments.

Some important points of principle are at stake here, and it is no surprise that the matter has become the centre of a controversy. The dilemma facing Congress is this. On the one hand, it would make no sense to have a patchwork of state and local controls on recombinant DNA research so that experiments were regulated more tightly in one city than in another. Genetically modified micro-organisms, after all, would not respect political boundaries, and a uniform set of national (or, preferably, international) controls would therefore make scientific sense. But on the other hand, the debates which have resulted in state and local governments adopting their own regulations have witnessed considerable public participation in scientific decision-making and the forging of new links between universities and their surrounding communities—ideals often given lip service but seldom put into practice. If the federal government takes away the right of local governments to set their own recombinant DNA regulations, it would risk stifling such developments. Moreover, there is some concern about the political implications of usurping a community's right to decide whether potentially hazardous activities should be permitted in its midst.

Needless to say, the scientific community has come down heavily on the side of federal pre-emption. Indeed, some scientists have publicly stated that they would support federal legislation only if it establishes uniform national regulations. The most prominent statement of such a position came late in April, when the National Academy of Sciences approved a resolution urging Congress to write a provision into the recombinant DNA bill specifically stating that federal controls would over-ride all local regulations. The Academy's resolution, it is

worth noting, was endorsed by Robert L. Sinsheimer, of Caltech, a leading critic of current guidelines governing recombinant DNA experiments.

But there has also been weighty testimony from a few scientists and from state and local officials, who have argued that the intervention of local governments in the recombinant DNA debate so far has been beneficial and there is no reason to expect that arbitrary or excessively strict local control will be adopted in the future. Every state and local government which has acted so far has endorsed the NIH guidelines, added a few minor additional precautions, and adopted procedures to enforce them. Even in Cambridge, where town-gown relationships had been notoriously bad, the city council approved recommendations, put forward by a citizens' committee, allowing recombinant DNA experiments to go ahead at Harvard and MIT essentially under the NIH guidelines. The report of the citizens' committee, in fact, provides an excellent example of how a group of lay people can participate effectively in scientific decision-making.

Is it therefore possible to establish uniform national controls without shutting off legitimate and healthy local inquiries? Possibly. Although some key legislators are hanging firmly to the notion that states should be given free licence to do as they please, a consensus seems to be developing in support of a scheme which would allow local changes to national regulations only under special circumstances. Perhaps more important, the scheme would provide local communities with an opportunity to have some input into national regulations.

It would work like this. The Secretary of Health, Education and Welfare (or whoever administers the national regulations) would have to approve local changes to the national rules. Approval would be given only if the local regulations are more strict than the national rules and if the local government can demonstrate that there are special local circumstances or that they are necessary to protect public health. Opportunity would be given for public hearings on the proposed changes. In practice, if a local government can make a good case, it would be likely to trigger changes in the national rules.

Although the arrangements would limit the powers of local government in the recombinant DNA debate, it would give them more authority than they have in areas such as radiation standards and the regulation of food additives. In short it represents a reasonable compromise between total federal pre-emption and the possibility of widely varying local controls. □

Under a cloud of committees

From Sydney, Peter Pockley updates some recent developments in Australian science policy

THE science-and-politics scene in Australia in the first half of 1977 has been remarkable only for much running on the spot with accompanying huff and puff. The symptoms are characteristic of SIC, the Syndrome of Inquiry and Committee, which, whether caught adventitiously or implanted deliberately, is manifest through a distinct brake on progress.

Those looking for a plot behind every move of the present conservative government might adduce SIC as evidence of a concerted move to downgrade the national science effort, the end result being disastrous attrition of the research dollar through galloping inflation before any substantive action occurs. But, on unravelling who is doing (or not doing) what among the dozen or so federal government departments with a major stake in science and technology, it is not surprising to find little more than a classic case of uncoordination.

One positive aspect of SIC is the appearance it gives of greater sympathy within the Liberal/Country Party government towards science, notably its applied aspects, than obtained within its Labor predecessor, in spite of the fact that under Labor science policy discussions were more public than before. After 18 months in office, though, the Fraser government's interest is still expressed only by SIC and the maintenance, for the time being, of the status quo. Everyone now expects the funds for science to remain very tight while high inflation (11–15%, depending on time-scale and assumptions) and high unemployment (5.5%, the highest since the Depression years) dominate the economic climate. Nonetheless, there are some government inquiries and committees which have the potential, at least, to affect constructively the course of events.

Breathing space

Late last year, a three-man Committee of Inquiry was established to look thoroughly into Australia's research colossus, the Commonwealth Scientific and Industrial Research Organisation (CSIRO). The full-time Chairman, seconded for the purpose from the Australian National University, is Professor Arthur Birch, an organic chemist noted for his contribution to the contraceptive pill. The other two members of the committee are a financier and an industrialist. Their appointments caused some tremors that the

government was intending, through the inquiry, to commercialise CSIRO by demanding short-term financial benefits from its research.

The final clause of the comprehensive terms of reference for the inquiry required the committee to "examine, report, and make recommendations on the extent to which and the means by which programs of the Organisation could attract revenue both to support the conduct of ongoing or intended research and also in return for results achieved in research".

The inquiry, though, ranges far wider than this. While it was not intended as a mere cost-benefit study of the operations of CSIRO's 37 divisions and 100-plus operations and \$140 million-plus budget, the pressure was on the members to come up with an interim report early in the year. The urgency was felt because of the imminence of the retirement in March of CSIRO's Chairman, Sir Robert Price (formerly Dr Jerry R. Price). The inquiry was asked to answer the question of what kind of person is needed to head the organisation, but an organisation that before long would presumably have some new terms of reference from the government as a result of the inquiry's own recommendations, which would have been either tentative or unframed at that time.

The government solved the inquiry's dilemma by appointing, for 12 months only, a new chairman in Mr Victor Burgmann, a long-standing member of CSIRO's Executive. The inquiry now has some breathing space for its major tasks, on which it was originally expected to report to the Prime Minister by the end of July.

Professor Birch says the inquiry is "not trying to put a few band-aids on CSIRO, but is taking a hard look at the whole set-up—where it fits in between universities and industry, and between Commonwealth and State departments and instrumentalities. While the benefits from cost-benefit analysis of CSIRO's research will be very hard to measure, we are making strenuous efforts to gain a good idea of them."

The Prime Minister showed his close interest in the inquiry by issuing the commission himself and, although CSIRO is responsible under its Act to the Minister for Science, Senator James Webster, the report will go to Mr Fraser.

Professor Birch says he has no political connections and he hopes the in-

Malcolm Fraser, Prime Minister

James Webster, Minister for Science

quiry's recommendations ("not gospel from heaven") will be acceptable to both sides of Parliament, for he sees CSIRO's operations as "lying outside the range of normal party politics". Nevertheless, given the continuing silence of the Labor Party on matters scientific, it is likely that Mr Fraser will be able to remould CSIRO's terms of reference to his own liking.

Going autonomous

The longest running stage show in Australian science—the on-again, off-again saga of a science council in various costumes—has at last been concluded with an announcement that the independence, permanence and stability of a statutory authority would be granted to ASTEC, the Australian Science and Technology Council. ASTEC proper, however, still has to await the presentation and passage of legislation through Parliament.

At least ten years of lobbying of successive Prime Ministers and Ministers for Science finally bore fruit when Mr Fraser announced on 19 April that he had accepted, in large measure, the recommendation of the Interim

(continued on page 479)

Uranium uncertainty

THOSE on either side of the nuclear power debate who were hoping for a clear 'stop' or 'go' for uranium mining in Australia and uranium export have been left disappointed by the second report of the Ranger Uranium Inquiry. The report, prepared by Mr Justice Fox of the Australian Capital Territory Supreme Court and his two fellow commissioners, was published on 25 May by the Australian Government Publishing Service.

It included several surprises for the speculators, as indicated by the wild fluctuations in the share market for uranium mines immediately after the report's much publicised release. On the specific problems of mining uranium in the Northern Territory, the report, like its predecessor handed down in October 1976 which dealt more with the global issues of safeguards and controls, has left the ball firmly in the government's court.

- There is something in it for the uranium lobby. The Ranger mine is given a cautious go-ahead, though under much stricter and very specific (hence more expensive) conditions regarding environmental control.

- There is something in it for the environmentalists. It is recommended that "as proposed, and in the land setting which was proposed, the Ranger project not be allowed to proceed". Further and larger mines nearby in the uranium-rich Alligator Rivers province, the development of which was also halted pending the Ranger report, are recommended

"not to proceed, at least for the time being". The main mines delayed by the proposed sequential development are the Noranda and Jabiluka mines.

- There is even more in it for the aborigines whose claims to land in the area cover most of the uranium province. The report is strongest of all on this matter, recommending a trebling of the Kakadu National Park to cover the entire Alligator Rivers region, yet warning that the greatest threat to the environment and particularly to the welfare, well-being and culture of the Aboriginal people, might prove to be the large white population which the mining ventures might bring.

The Prime Minister, Mr Fraser, left for overseas on the day after the report's release. He has signalled that his discussions with President Carter and other leaders have uranium policy high on the agendas, especially since Mr Carter's staff have been saying, somewhat paradoxically for the layman, that the new US policy for containment of nuclear proliferation relies heavily on the export of Australian uranium.

While the Australian government has made no formal decision and has announced that a full debate will not occur in Parliament until the Budget session in August, few people doubt that mining will be allowed to proceed. The only real question is which mines will start and when. Meanwhile, the public relations and political lobbying of the pro- and anti-nuclear

forces will intensify, each side claiming to summarise accurately in a few words that the highly complex and voluminous Fox report supports their side.

On a wider front, however, Australia has joined the political bandwagon that is energy more by reason of following the leader (that is the USA and Europe) than of any urgency felt imperative locally. Australia is blessed with vast black and brown coal deposits, there are some modest oil wells and reasonable gas fields, and there has been a government policy of keeping down the prices of petroleum products. Despite the need to import increasing quantities of crude oil, few Australians have felt the effect of a genuine scarcity of energy. Politically, energy has not yet equated with votes.

Nonetheless, the Deputy Prime Minister, Mr Doug Anthony, has seized on the energy question as his rightful responsibility under his role as Minister for National Resources. His views on the matter are now accorded respectful space in the press, a good start to making energy a real issue. But, while there is much talk of "moving towards an energy policy", nobody is really saying what it is likely to be.

Mr Anthony has shown willingness to listen to expert opinion, and has set up an 18-person National Energy Advisory Committee chaired by top metallurgist, Dr Howard Worner. It is charged with advising on Australia's energy reserves, supply and demand, future costs, economy of use, research and technology.

In a welcome move, Mr Anthony has decided to release the Committee's advice for public information and debate. The first advice, released in May, commented with fulsome praise on President Carter's message to Congress on energy. It said that, despite obvious differences arising from the levels of consumption, "the basic conservation principles expressed in President Carter's statement are, in the Committee's view, directly applicable to the Australian situation". It advocates, for Australia, smaller cars, more effective use of public transportation, reduction of wastage, use of surface rather than air transport, rail rather than road transport where appropriate, and lowering speed limits on open roads. As with the Fox report, the government has given no indication of action to follow this advice.

Peter Pockley

Mary Kathleen uranium mine, circa 1961

Astronomy's own cloud

Meteorology and astronomy, two areas which seem to boil over periodically and publicly, have been placed under inquiry by the Australian Department of Science. Both committees of inquiry have been under way since late last year and were charged with reporting to the Minister for Science, Senator James Webster.

Neither report has been completed nor been made public. Some anxiety on this point is evident. The Secretary of the Department of Science, Sir Hugh Ennor, has only a few months left before retirement and, being the forceful character that he is, he doubtless wants to wrap up his work with the weather and star men safely settled for a while.

Relations between the Australian Bureau of Meteorology, headquartered in Melbourne, and the Canberra-based Department of Science have been tense ever since the bureau was transferred to the Department's responsibility under the Labor government. The committee was set up following regular and damaging leaks in the press of alleged confrontations between the bureau and the department. Its terms of reference included "making recommendations on the Head Office and Regional Organisational structure", but other terms cover all the bureau's functions.

The bureau has operated under its present act, the Meteorology Act, since 1955. The accompanying degree of independence was important to its Director, Dr Bill Gibbs, and to many users in this vast land mass where the rural industry and aviation services are peculiarly dependent on sound and comprehensive weather advice. The inquiry was seen by many as being the only method of resolving the bureaucratic conflicts. Significantly, the three-man committee did not include any professional meteorologist.

Things are a little different in astronomy. Ever since the early 1960s when Australia leapt into the big league of astronomical nations with the building of the giant 64-metre radio dish at Parkes, New South Wales, a clamour for large facilities has been maintained, and to a reasonable extent satisfied. From the astronomer's point of view, their requests made good sense. Despite its relatively low terrain, Australia provided the only geologically and politically stable platform in the southern hemisphere for observing stars obscured to northern telescopes.

To a certain extent the argument of uniqueness is no longer as strong

following the construction of some large telescopes in the South American Andes and Hawaii—at which stage other arguments take over, about maintaining a world lead, keeping the best scientists at home, and the prestigious PR that a nation gets from big telescopes. To back these arguments, the Australians now have a magnificently timed and very visible example of how astronomical research can lead to necessary (and profitable) application on Earth. At the end of March the Australian-developed 'Interscan' system for aircraft landing control in three dimensions was officially adopted as the next international standard. Interscan beat all comers from the USA, the USSR, Britain and Europe and is now the basis of a burgeoning industry. The microwave system was developed by the radioastronomers of the CSIRO Division of Radiophysics.

The Parkes facility was expanded in the mid-1960s to become an interferometer, and the main dish has recently been refigured at its centre to accept millimetre wavelengths. Among the other facilities around the country, the University of Sydney built its own radio interferometer—the so-called 'Mills Cross', named after its designer, Professor Bernard Mills—and an optical interferometer, Professor Robert Hanbury Brown's Stellar interferometer at Narrabri in northern New South Wales (now at the end of its useful life). CSIRO's Division of Radiophysics opened a magnificent solar observatory at Culgora, also in northern NSW, with Dr Paul Wild's Radioheliograph, together with optical solar telescopes of another division. Meanwhile, the Australian National University was expanding its optical observatory at Siding Spring in northern NSW, and in 1974 the joint Anglo-Australian Telescope Board opened its 3.9-metre telescope on the same mountain, then the largest optical telescope in the southern hemisphere. Beside it, the British also now operate a 1.9-metre Schmidt sky camera.

Enough for a nation of nearly 14 million people and few astronomers? Not so, said the astronomers, and asked for more—here remains our one chance of maintaining across-the-board, world-class excellence in a branch of science. Because of the sums involved for new facilities of significance, leading astronomers the world over have had to become politicians, and the Australians are no dullards at this game. Every minister responsible for science in Australia

has eventually cried for mercy—continuance of the ad hoc lump-sum handouts of earlier days could no longer be justified, they said, without the unanimous recommendation of an expert committee.

And so began an unceasing stream of references from ministers to committees which either never reached unanimity or had to be replaced because of political change. The latest act has been the establishment of yet another committee to end all committees, this one by Senator James Webster.

The committee, it was announced, was to be "an interdepartmental committee (IDC) chaired by the Department of Science. The Committee comprises representatives of the Public Service Board and the Departments of Education, Science and the Treasury". The IDC (of non-astronomers, it will be noted) was charged with inquiring into the range of astronomical research and facilities.

The public servants of the IDC would clearly be responsible for making the recommendations to the minister. However, an "expert sub-committee" was named to assist the IDC. And there was the rub, as far as the scientific community was concerned. For, while the names of the sub-committee were publicised (it is chaired by Professor Kevin Westfold of Monash University), the IDC remained anonymous in the official announcement.

The gentle inquirer, however, would soon be told that the IDC was chaired by the redoubtable Sir Hugh Ennor, and included the well-regarded Secretary of the Department of Education, Mr Ken Jones, and some named but lesser fry. Yet the very possibility of some private shenanigans continued to worry some participants. The influential Academy of Science is understood to have initially refused to make a submission over the Academy's name.

As far as the astronomical politicians were concerned, an IDC was quite clearly a most inappropriate vehicle for assessing their aspirations. For the government, however, it has kept the lid on some vocal people for a while. Yet the government has let itself in for at least one more round by announcing that the IDC's report (intended for the Minister for Science) would be referred to ASTEC "for comment". And ASTEC reports to the Prime Minister, who is charged in most cases, and certainly including this one, with releasing their reports.

Peter Pockley

The federal Inquiry into Education and Training, which is trying to relate post-secondary education and the job market, will also impinge on science, though not directly. Professor Bruce Williams, an economist who is Vice-Chancellor of the University of Sydney, is chairing the Inquiry which is being taken very seriously indeed by the three tiers of universities, colleges of advanced education, and technical and further education.

If the current political cry for 'relevance in education' (that is less unemployment among secondary and tertiary education leavers) has any pull left by the time the Inquiry reports next year, then a reduction in the research and scholarship activity at universities relative to vocationally oriented training is possible. However, the appointment of a resilient university man as chairman is reasonable protection for the university position.

Siding Spring Observatory (see opposite)

Parkes radiotelescope (see opposite)

(continued from page 476)

ASTEC about its continuation*. Mr Fraser's statement is worth quoting at some length:

The functions of ASTEC are to advise the Government on science and technology, including

- the advancement of scientific knowledge and the development and application of science and technology in relation to the national well being;
- the adequacy, effectiveness and overall balance in the national effort in science and technology in Government, industry, education and other sectors of the community;
- the assessment of gaps and overlaps in science and technology in Australia;
- the identification and support of new ideas of science and technology likely to be of national importance;
- the practical development and application of research discoveries and the fostering of technological innovation in industry; and
- the means of improving efficiency in the use of resources related to science and technology.

The Council will have a strategic role in assisting the Government to encourage Australian science and technology to meet the nation's needs and objectives. It will have no executive responsibilities but will be able to advise on operational arrangements.

ASTEC's knowledge and analysis of science and technology will be valuable to many arms of Government. And the Government expects the Council to inform itself and be informed of relevant Government policies and to take into consideration economic and budgetary implications in discharging its functions.

ASTEC will draw on existing Departments and Agencies for the expertise, knowledge and assistance necessary to enable these functions to be discharged effectively. But this will in no way compromise the independence of ASTEC.

ASTEC has been charged first with preparing a long-overdue report on the present state of science and technology in Australia. Information about Australia's effort has been so fragmented, particularly in the government arena which dominates national R&D expenditure, that the very thought of deriving coherent policies from such information boggles the mind. This task may well be measured in years and is almost certain to out-run the life of the present Parliament, which has only 18 more months at the most.

ASTEC is thus unlikely to influence the science funding sections of the August 1977 budget, framing for which is already well advanced (to cries of "horror budget cuts"), and may hardly have sufficient time to influence the

1978 budget and the present government's final burst of legislation before facing the people again.

As anticipated in earlier reports, the permanent ASTEC reports to the Prime Minister. Its small secretariat is established within the Prime Minister's own Department. That these moves will be popular among scientists and technologists is quite certain. An analysis of the views expressed in submissions to the Interim ASTEC showed that 46 of them favoured ASTEC reporting to the Prime Minister, 6 to a Ministerial Committee, 3 to Cabinet as a whole, 4 'others', and a bare 2 to the Minister for Science. Hardly a resounding vote of confidence in the political clout of the scientists' 'own' Ministry.

The government intends that ASTEC's reports will be made public "unless there are overwhelming reasons in the national interest for not doing so" (in other words, when the security boys cry stop). Meanwhile the Australian Academy of Science, whose influence over government went into a small, temporary decline under Labor, has emerged triumphant with the appointment of its current president, Professor Geoff Badger, as part-time Chairman of ASTEC, and its immediate past president, Professor Sir Rutherford Robertson, as Deputy Chairman. Professor Badger, an organic chemist, is now a research professor at the University of Adelaide, having recently completed a ten-year stint as its Vice-Chancellor. He is firm, persuasive and skilled at the kind of politicking ASTEC needs for success.

While it was officially said that members of ASTEC are not selected as representatives of particular interest groups, it is not hard to see the influence on the present government of the major areas of Australian industry. The rural, steel, mining, chemical, electronics and paper industries all have senior executives on ASTEC, including three managing directors. Just how much time such busy men (there are no women among ASTEC's fifteen members) can devote to the detailed collection and assessment of information across the whole spectrum of science remains to be seen.

In theory, there appear to be few restrictions on ASTEC's coverage of the science and technology scene. The Interim Council's report set itself against covering the social and behavioural sciences, but argued for the inclusion of both the defence and health sciences. In Labor's terms of reference for an earlier Interim ASTEC, social science was in, but defence and health were out. Whether these items will be specified in the legislation is not known as yet. □

Scientists think too

SIR,—Thank you for referring to my recent Presidential Address to the American Physical Society (28 April, page 759). However the irony implicit in your references to my address does not escape me. I disagree with you especially when you closely couple some of my words to "the recent frenzy to project science as still valuable".

Come off it. On rereading my address and listening to a recording I find nothing frenetic about it. In fact I delivered the address in an old sweater. I figured that a President of the American Physical Society, nicknamed Willy, was not to be outdone by a President of the United States, named Jimmy. The tape tells me I got some laughs but mainly I was in dead earnest. Sure, scientists are thinkers but our public image is just that—and long hair too! If society is to reach a solution of its present horrendous problems it must permit the scientist to be more than thinker, consultant and adviser. It must let him be a doer in the sense of executive, manager, legislator all the way to trouble-shooter and fix-it man. Society seems to have forgotten what happened in the winning of World War II and is now wasting a potent resource. You delude the public and discourage students by harping on the image of the scientist as the thinker. It obscures the role the scientist can perform as man of action.

WILLIAM A. FOWLER

Past President,
American Physical Society,
Caltech, California

SIR,—While agreeing with the sentiment of your advocacy for the role that could be played by scientists in the affairs of the nation (28 April, page 759), your suggestion that the mass media should take it upon itself to act as a public relations vehicle for science is both a serious indictment of scientists, and a misconception of the role of the media.

Science is undoubtedly the most highly funded cultural activity of today, yet precious little if any of this funding is devoted to developing the communication talents of its practitioners. British scientists, in my experience as a programme producer, are no more nor less talented as broadcasters than any other group of pro-

fessional people. They are certainly no more nor less perceptive about the affairs of the nation than say lawyers, historians, philosophers. Your proposal that the media create an image for scientists seems to be asking that the media take part in a cover-up campaign. You're asking us to hide a failure in the training of scientists.

You write that "very few scientists are allowed to express their own views in any extended way". I could quibble with your words "very few", but I would like to draw your attention to some science broadcasts you appear not to hear. For example, the fortnightly *Scientifically Speaking* on Radio 3 is the kind of programme you say is missing. In a year's broadcasts about 30 notable scientists (not to my mind "very few") take part usually in a 45 minute conversation. Through the questions of the interviewer, even the totally uninitiated yet intelligent listener is taken to the epistemological frontiers of science. Sydney Brenner, Leon van Hove, Nick Humphrey, D. T. White-side and B. F. Skinner—all participants in recent editions of *Scientifically Speaking*—falsify your general proposition that radio does badly in portraying the scientist as thinker. In broadcasting, what achieves impact is high programme standards, not saturation of the wavebands with merely adequate broadcasts mounted to present an image.

There also exists on Radios 3 and 4 another admirable vehicle for scientists as homo 'sapiens'—the scripted talk. I am not inundated with unsolicited ideas. You might well argue that we are too restrictive in allowing speakers the freedom to choose their topics. I would counter by drawing your attention to the long running Radio 3 series *Personal View*, transmitted on alternate Saturday evenings. In the course of four, 20-minute *Personal View* talks, the speaker is encouraged to reflect on topics of his own choice. Over the past three years, the three scientists who have given *Personal View* series have set a high standard for the others to come. Dauntingly, it seems, because many of those approached are put off by a brief that asks them to argue on topics that are in the public eye.

Surely scientists do have views, but why are they so often inhibited when offered a platform to expose their thoughts on issues outside their field of

professional enquiry? Let's not have image-building. Broadcasters are not public relations men; let's have the real article.

DAVID PATERSON

BBC, London, UK

T. H. Huxley, a self portrait

SIR,—I found this self-portrait of T. H. Huxley among the effects of Mr W. D. Bradfield, assistant to Sir William de W. Abney, a former physics professor at Imperial College, best known for his researches in colour vision.

In his autobiography T. H. Huxley states that he inherited his faculty for drawing from his father but never received any formal training. Sir Julian Huxley considered his grandfather's sketches almost as finely executed as those of Leonardo da Vinci.

Bradfield photographed the drawing and the back of the photograph reads "photograph of pencil drawing of Professor Huxley. Drawn by Professor Huxley in Captain Abney's memo book". Abney joined the Science and Art Department, South Kensington in 1877 and Huxley resigned his appointment at the Royal School of Mines in 1885. The sketch was therefore probably drawn sometime during this period when Huxley was in his mid-fifties.

The protein explosion

from Denis Bray

THOSE cell biologists who feel that the flux of information in their subject is already too high will view the latest development in gel technology with mixed feelings. For where the typical SDS gel of two years ago had some 20 well resolved bands, the two-dimensional gels that are presently *de rigueur* for the analysis of protein mixtures have several hundred. The amount of information obtained from one sample is thus appropriately, squared. The new method, devised by O'Farrell (*J. biol. Chem.* **250**, 4007; 1975), consists in electrophoresis in the presence of urea and ampholines in one dimension, and in SDS in the second. The proteins move into positions in a two-dimensional array determined by the independent parameters of isoelectric point and polypeptide size.

The system is potentially able to resolve 7,000 proteins, and although in his paper O'Farrell modestly admitted to having achieved only 1,100 from a bacterial lysate, the limitation is more likely to be in the *E. coli* genome than in his technique. From the rapidity with which it has been exploited the method obviously satisfies a long-felt need, and for many purposes it replaces a number of more complicated methods in which protein bands from gels are identified by proteolytic or chemical cleavage. It has already been widely applied and has shown even familiar biological materials to be more complicated than anyone had imagined—the flagellar axoneme for example, has over 100 components (Piperno *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 1600; 1977). The worry that the electrofocusing step might generate artefactual spots may have existed at the early stages but has gradually disappeared with use. It is explicitly disproved by such striking demonstrations as that of Milman *et al. (Proc. natn. Acad. Sci. U.S.A.* **73**, 4589; 1976), that a single genetic defect in HeLa cells affects only one spot on a 2-D gel. One is forced to conclude that each spot corresponds to one protein, and in consequence that

there are a very large number of proteins about which we know nothing at all.

Another, ostensibly unrelated, way to examine proteins is with fluorescent antibodies. This established procedure, developed by Coons more than 35 years ago, received its cell-motility debut quite recently with the isolation of anti-actin and its use to show microfilament bundles within fibroblasts (Lazarides & Weber *Proc. natn. Acad. Sci. U.S.A.* **71**, 2268; 1974). Since then, chorus-lines of glittering actin, myosin, filament protein, or LETS protein—to name a few—have brightened the biological journals in such routines as mitosis, transformation or colchicine treatment. Each pattern is characteristic of the protein and situation, even—according to the provocative suggestion of Albrecht-Bühler (*J. Cell Biol.* **72**, 595; 1977)—to the point of showing familial resemblances between daughter fibroblasts. The technique is not restricted to major protein components; indeed, because its sensitivity is uncontrollable even trace contaminants can give a sizeable response. Just how sensitive the method is will depend on the precise conditions, but some idea may be gained from the fact that a few hundred thousand antigen molecules on a lymphocyte surface give an adequate response. From this it should be possible to see 1,000 molecules of an antigen on a small area.

The two approaches of gel electrophoresis and immunological localisation have often been combined, in two recent reports of elegant work on muscle for example. Antibodies to C-protein (named for its position on an SDS gel) were prepared by Craig and Offer (*Proc. R. Soc. B* **192**, 439; 1976), and found to bind nine transverse stripes on either side of the A-band of striated myofibrils. That is, nine stripes were labelled in fibrils close to the edge of the muscle fibre, but only seven or eight in fibrils closer to the centre. The difference was revealed as being due to two other antigens in the original C-protein mixture, and by absorption, one or two stripes of the original nine could be stained. An even closer relationship between the techniques exists in recent

work on the 100 Å filaments of smooth muscle. These were recently prepared in good yield by Cooke (*J. Cell Biol.* **68**, 539; 1976), and by Small and Sobieszek (*J. Cell Sci.* **23**, 243; 1977), and are made of a protein with an apparent molecular weight on SDS gels of about 50,000. If this band is excised and the protein it contains injected into a rabbit, antibodies are obtained that stain not only smooth muscle, but the Z-disc and inter-fibrillar regions of striated muscle, and the areas of cell-to-cell contact in heart (Lazarides & Hubbard *Proc. natn. Acad. Sci. U.S.A.* **73**, 4344; 1976). When it is examined on 2-D gels this protein reveals two components which seem to be the same regardless of the muscle type. (Izant & Lazarides *Proc. natn. Acad. Sci. U.S.A.* **74**, 1450; 1977).

The synergism between gels and antibodies illustrated by such work is impressive but short of the ultimate. For surely it is entirely feasible now to extract proteins from large 2-D gels, raise antibodies to them, and use these to locate and purify the native protein? The possibilities then become awesome. If a technique in which a thousand proteins can be resolved is combined with one that can detect a thousand molecules, it could be like bringing two sub-critical masses of fissionable material together. What then would limit the isolation of new proteins, and how many biochemists would have to be applied, and for how many years, before the end was reached? Perhaps it will depend, ultimately, on how many proteins there are in all. The thousand spots seen by O'Farrell in extracts of *E. coli* must have represented the lion's share of that organism's proteins and if mammalian cells have of the order of 10,000 proteins—in keeping with the genetical estimates of 5,000 for *Drosophila* and 2,000 for *Caenorhabditis*—then there will be some hope of a complete account. But what if the geneticists are wrong and most of the potential for 100,000 proteins in the non-repetitious DNA is expressed? And what if someone invents a 3-D gel? Then, surely, it will be time to call a halt and to show the responsible attitude recently developed towards plas-

Denis Bray is a member of the MRC Unit of Cell Biophysics at King's College, London.

mid research. Perhaps the discovery of new proteins could be confined to rigorously controlled (P4) conditions, or a two-year moratorium on gels could be held. At least that would let us catch up with the literature. □

Metabolic studies using ^{31}P NMR

from G. E. Chapman

THE state of proton NMR spectroscopy of biological macromolecules is somewhat akin to that of X-ray crystallography before methods of solving the phase problem had been devised. There is an embarrassment of detail, with as yet no reliable methods of interpreting it in terms of molecular conformation, though it is relatively simple to work backwards from a known structure to the observed spectrum. It is not surprising therefore that much effort is now being directed towards the NMR study of those heavier nuclei where there is less detail in the spectra, and interpretation is easier.

The increased use of ^{31}P NMR in biological research in the past year or two owes much to magnet development. In the continuing search for greater sensitivity, the NMR spectrometer designer has usually opted for higher magnetic field strengths, stretching superconducting magnet technology to the limit. However, there are indications that increasing magnetic field strengths are not achieving increases in sensitivity for the heavier nuclei when they are incorporated in macromolecules. Hence one alternative development has been that of magnets capable of maintaining very homogeneous fields over large sample volumes. This is particularly advantageous where the sensitivity is limited by the concentration of the sample rather than by the amount of material available. The following recent work has been made possible by these developments.

The monitoring of phosphate metabolite levels in living cells and tissues by NMR, being non-destructive, is aesthetically more pleasing than the conventional freeze-clamp techniques that have been used in the past by biochemists. However, it could be argued that both methods give the same results, and that a great many freeze-clamp experiments can be done for the price of buying and maintaining a modern advanced NMR spectrometer.

G. E. Chapman is a member of staff at the Biophysics Laboratories, Portsmouth Polytechnic

This question probably cannot be resolved at present. A hybrid of the two methods has recently been illustrated, where the phosphate metabolites from the extract of a quick-frozen heart were analysed by ^{31}P NMR (Garlick *et al.* *Biochem. biophys. Res. Commun.* **74**, 1256; 1977).

One type of measurement by ^{31}P NMR in living cells however is giving results which have not been obtained reliably and accurately by other methods. This is the measurement of intracellular pH. It is achieved by observation of the inorganic phosphate chemical shift, which changes with pH in the region of neutrality due to its second acidic dissociation, and is capable of considerable accuracy (better than ± 0.02 pH units near pH 7). The intracellular pH of living *Escherichia coli* suspensions has been measured in a variety of metabolic conditions (Navon *et al.* *Proc. natn. Acad. Sci. U.S.A.* **74**, 888; 1977). It was shown that the intracellular pH was consistently higher than that of the external medium during respiration, but if respiration ceased, then the pH values rapidly equalised. This supports the hypothesis that an outward directed proton pump mechanism operates during respiration. Experiments on chromaffin granules (the catecholamine-storing vesicles of the adrenal medulla) by ^{31}P NMR also used chemical shifts to detect pH changes within the vesicles (Casey *et al.* *Biochemistry* **16**, 972; 1977) though in this case the resonance monitored was the γ phosphate of ATP rather than inorganic phosphate.

Although *in vivo* experiments are inherently more spectacular than *in vitro* ones, from the view point of the biologist, the latter type of study can be better controlled. Investigations of the important metabolic regulatory enzyme system glycogen phosphorylase, is a classic example of the importance of *in vitro* studies of metabolic processes. There are at least five phosphate compounds associated with the enzyme as substrate, cofactors and allosteric effectors. It has been investigated by ^{31}P NMR in the past, but the high molecular weight has meant the use of very high protein concentrations to achieve adequate molar concentrations of the bound phosphates, which in turn has given rise to considerable viscous broadening of the resonances. This has recently been overcome by the use of large sample volumes, and in the latest paper (Feldmann & Hull *Proc. natn. Acad. Sci. U.S.A.* **74**, 856; 1977) the role of pyridoxal phosphate in the enzyme complex has been investigated. In such an NMR experiment, one would expect some of the resonances to overlap, and the authors overcome

this by the ingenious device of using thiophosphate analogues, where these were known to be active in the enzyme system. Thiophosphates have chemical shifts about 40 p.p.m. downfield from those of the corresponding phosphate compounds. Hence the resonances of all the phosphates could be resolved. In this way, much was learnt about the interaction of the molecular species involved.

The above exemplifies, I believe, how good communication and teamwork between the biochemists and physical technique specialists can advance the application of a technique to biological problems. Here the interdisciplinary approach is paying handsome dividends. □

The nucleotide-binding fold revisited

from C. C. F. Blake

SOME time ago in these columns (*Nature* **250**, 284; 1974) I discussed the significance of a particular protein fold that had been noticed by Rossmann to constitute part or all of the structures of four NAD-dependent dehydrogenases and a number of other enzymes, some but not all of which also bind nucleotides. In lactate-, alcohol-, and glyceraldehyde-3-phosphate dehydrogenase, the fold corresponds to a separately organised NAD-binding domain, that in each molecule is linked to a second domain whose tertiary structure is specific to the particular enzyme. On the basis of this structural pattern Rossmann and his colleagues (*Nature* **250**, 194; 1974) proposed that the NAD-binding domains had evolved by divergence from a common ancestor, and had been incorporated into the dehydrogenases by gene fusion with another protein fragment, different in each enzyme, that became responsible for that enzyme's particular catalytic and substrate binding properties. Potentially this proposal provides a profound insight into the evolution of those groups of enzymes that catalyse the same type of reaction, often using common cofactors, but working on quite different substrates. The key to the proposal is the assumption that an extensive structural similarity, unsupported by sequence homology, represents the relic of a very distant gene duplication. However, so little is known about the factors controlling protein

C. C. F. Blake is a lecturer in Molecular Biophysics in the University of Oxford.

structures that it is very difficult to draw the essential distinction between homology and analogy. Since in the past few months three papers have appeared that in various ways bear on the problem of the significance of the nucleotide-binding fold, it seems worthwhile to return to the topic.

Describing the tertiary structure of phosphorylase α , Fletterick *et al.* (*J. biol. Chem.* **251**, 6142; 1976) note that a part of its 800-residue polypeptide chain is folded into the nucleotide-binding pattern, and demonstrate its close similarity to the NAD-binding domain of lactate dehydrogenase. In agreement with the prediction of Rossmann's proposal, Madsen and his colleagues have observed that the fold is the location of a binding site for adenine or adenosine that is close to the site for the adenine ring of NAD in the equivalent region of lactate dehydrogenase. Unfortunately the significance of this binding site is not known, and the site for the known allosteric effector AMP, is elsewhere in a region whose structure is quite different from the nucleotide fold. Nevertheless, the discovery of the fold in yet another enzyme, associated with nucleotide binding, must strengthen the hypothesis considerably.

One of the features of the fold that was instrumental in its discovery was that the usually helical loops that sequentially link together the six-stranded parallel β sheet, were all arranged in a right-handed sense, thus giving rise to a characteristic distribution of connections above and below the sheet. At the time both right- and left-handed turns were thought to be allowed, suggesting that the repeated occurrence of a particular pattern in the disposition of the connections was highly significant. Sternberg and Thornton (*J. molec. Biol.* **105**, 367; 1976) have now shown that this view is incorrect. By analysing all known proteins in terms of the disposition of the loops linking adjacent β strands, they have found that in 57 out of 58 cases the connection has a right-handed sense. Furthermore they have produced a soundly based argument that the right-handed connection is a natural consequence of the steric factors imposed by the twist of the β sheet, which Chothia (*J. molec. Biol.* **75**, 1295; 1973) has shown, can itself be understood in terms of the interactions within the individual strands of the sheet. This means that the five right-handed connections in the nucleotide-binding fold are not independent parameters, with which the fold can be defined, but are the consequence of good molecular packing. The removal of these parameters has dramatically reduced the figure of topological relatedness calculated by Schulz and

Schirmer (*Nature* **250**, 142; 1974) for a number of proteins in which the fold seemed to occur, to leave only the topologies of the cofactor-binding units of the dehydrogenases with a sufficient degree of relatedness to need a special explanation. Rossmann's hypothesis still stands then, stronger I suspect for having a number of dubiously-related enzymes stripped away from it by Sternberg and Thornton, leaving a solid core of structure whose relations have a firm functional foundation.

The most striking new addition to the catalogue of enzymes showing tertiary structural homology is pyruvate kinase, whose structure has been recently reported by Stammers and Muirhead (*J. molec. Biol.* **112**, 309; 1977). The structure of the 60,000 molecular weight subunit is divided into three domains, the largest of which is closely similar to the complete triose phosphate isomerase (TIM) subunit. As described by Banner *et al.* (*Nature* **255**, 609; 1975) the TIM subunit has a hitherto unique structure composed of eight parallel β strands forming a closed barrel in the core of the molecule, surrounded by helical connections, giving it an unusually simple, symmetrical organisation. This structure is sufficiently characteristic for there to be little doubt that it constitutes the central domain of pyruvate kinase. The active site of pyruvate kinase is located in an equivalent position to the active site of TIM, in relation to the common structure. These structural and functional similarities between pyruvate kinase and TIM are of the same order as those in the various versions of the nucleotide-binding fold, and should therefore in principle be treated in the same way. Is it then plausible that pyruvate kinase and TIM should have a common ancestor? The only thing that one can say is that despite the quite different kind of reaction catalysed by the two enzymes, their substrates are both 2-keto-trioses. Whatever arguments are applied to the significance of the nucleotide-binding fold; it seems that they must now also bear on the 'keto-triose fold' and *vice versa*; they stand, or fall, together.

Finally the structure of pyruvate kinase focuses attention on the very curious fact that while the four dehydrogenases whose tertiary structures are known show a significant degree of similarity to one another, the four kinases do not. Adenylate kinase is somewhat similar to a part of phosphoglycerate kinase (PGK), but does not seem to be significantly related; PGK itself almost certainly contains at least one, if not two, copies of the nucleotide-binding fold; pyruvate kinase is structurally related to TIM as we have seen; and hexokinase seems

to have a unique structure. The search for indications of enzyme families through structural similarities will continue, but it seems that any pattern that emerges is unlikely to be simple and clearcut. $\square$

Systematic behaviour of E1 decays in sodium

from P. E. Hodgson

THE electric dipole (E1) transitions in light nuclei have so far received little theoretical attention because selection rules often forbid transitions between the major components of the wavefunctions of the initial and final states, so that they depend on small components of the wavefunctions which are difficult to calculate. In spite of this, the experimental E1 transitions in ^{23}Na show a remarkably simple pattern that is quite different from that given by the simple rotational model. Recently Pilt has developed an alternative model that agrees very well with the experimental data for ^{23}Na and also for ^{21}Na . (*Z. Naturforsch* **32a**, 73; 1977).

The E1 decays in ^{23}Na take place between the lowest $1/2^-$ band and the ground state $3/2^+$ band. It is found that when the overall E^3 , dependence of the transition rates is removed a spin J state of the $1/2^-$ band decays preferentially to a spin $J+1$ state of the $3/2^+$ band. A completely different behaviour is predicted by the simple rotational model, which gives reduced transition strengths proportional to the squares of the appropriate Clebsch-Gordan coefficients.

It is most likely that such regular deviations from the simple rotational model are due to an interference effect, and Pilt suggests that this can be provided by mixing higher Nilsson orbitals into the ground state band. The most likely orbitals are those with spin and parity $1/2^+$ and those with the configurations [220] and [211] are the most probable. The E1 transition rate is then given by the absolute modulus squared of the sum of the appropriate Clebsch-Gordan coefficients, multiplied by weight factors, that is,

$$B(E1) = |(J/2 \ 11/J'3/2) + m_1(J/2 \ 10/J'1/2) + (-)^{J'-1} m_2(J/2 \ 1-1/J'-1/2)|^2,$$

where J and J' are the spins of the initial and final states, and m_1 and m_2 are the weight parameters which are related to

P. E. Hodgson is a lecturer in Nuclear Physics in the University of Oxford.

the degree of mixing between the $1/2^+$ and $3/2^+$ bands.

So far it has not been possible to calculate the mixing parameters m_1 and m_2 , but the model may be tested by using the experimental values of $B(E1)$ for two transitions to determine m_1 and m_2 , and then to use these values to calculate the $B(E1)$ values for the other transitions. Pilt did this for the transitions in ^{23}Na , and found that the reduced transition rates for the whole band are very well given by this model. The same analysis was applied to the transitions in ^{21}Na , and this also gave good overall agreement with the data, although it did not have such a simple pattern as that for ^{23}Na .

An attempt to calculate the mixing parameters from the Nilsson model was not successful; it was found that there is no value of the nuclear deformation that gives the observed distribution of transition strengths. It thus seems that a more detailed microscopic theory is needed to obtain a proper understanding of these quantities.

Even in its present form, with the parameters treated as adjustable and fitted to the data for each nucleus, the model can be very useful in correlating experimental data, and it could well be a useful method of determining the spins of high-spin states. It would clearly be useful to test its applicability to other nuclei, and this might show some systematic behaviour of the mixing parameters, which in turn might provide a clue to their microscopic interpretation. □

A tribe of mimics

From a Correspondent

BLENNIES are generally known as small, rather retiring fishes living in shallow water close to rocks or coral. Very many species are known in temperate and tropical seas but the latter contains the greatest number of species. A few are found in freshwater. Partly because there are so many nominal species, ichthyologists were exercised in attempting to assess their phylogeny, and for long the standard work on the group as a whole was J. R. Norman's provisional synopsis (*Ann. Mag. nat. Hist.*, ser. 11, 10, 793–812; 1943). More recently, V. G. Springer's study of the osteology and classification of the family (*Bull. U.S. natn. Mus.* 284, 1–85; 1968) has provided a major clarification and a useful overall classification within which Springer, and others, can tackle the smaller groups in the family.

The most recent is a revision of the sabre-toothed blennies of the tribe Nemophini by W. F. Smith-Vaniz (*Acad. natn. Sci. Philadelphia, Monogr.*

Origin of North China loess

from I. J. Smalley

CHINESE civilisation developed on the great North China loess deposits. Ho (*Cradle of the East*, Chicago University Press, 1975) has argued convincingly that this development took place in isolation, uninfluenced by the parallel progress in the Middle East. A major factor which did influence the growth of the early Chinese civilisation was the presence of the loess which was an ideal soil for the early farmers. The origin of this North China loess is still in dispute. Most of the other loess deposits in the world have glacial connections and their formation can be seen as part of a sequence of Pleistocene events, but the Chinese loess does not have an obvious glacial link.

The results of the first electron microscope observations of Chinese loess have now been published (Lu *et al. Geochimica* 47, 1976). These allow the Chinese workers to reject totally the Berg theory of *in situ* formation, but they still find themselves unable to accept totally a direct glacial connection. The grains observed are broken and have sharp edges, and silica precipitation and chemical etching are commonly observed on the quartz silt particles, which might have been subjected to relatively long weathering processes

before being transported to the loess accumulation areas. In the relevant areas the authors suggest that glaciation only occurred on mountain tops, and that this may have produced some loess, but they favour a distant western source for the majority of the material. No specific particle-producing mechanism is described.

It may be that in this case a longer than usual transportation stage was involved and that material was formed in distant glaciated regions and that the continuing aridity and the presence of mixed particle deposits in the post-Pleistocene times prevented the formation of stable loess deposits. In Europe and North America loess deposits form very close to the ice limits. The Lu *et al.* paper is an encouraging sign of the renewal of interest in loess sedimentology in China. It is a pity that those otherwise admirable data handlers, *Science Citation Index* and *Mineralogical Abstracts*, have not realised that in Chinese the family name (as used in references) comes first; so this important paper has been listed under Yanchou *et al.* which could cause some confusion.

I. J. Smalley is a lecturer in the Department of Civil Engineering at the University of Leeds.

19, 1–196; 1976); an excellent contribution to the systematics of these Indo-Pacific blennies. As a taxonomic work it is of fundamental importance for not only are 41 species in 5 genera fully described and figured, but 13 of these species are new taxa, recognised here for the first time. However, this paper is important not just because it is a highly competent revision, but because of the information about the life styles and behavioural relationships of this fascinating group of blennies.

The sabre-toothed blennies are so called because they all have a massive recurved canine tooth posteriorly in the lower jaw. Most species also have smaller caniniform teeth in the upper jaw. In the front of both jaws the teeth are small, closely-packed and incisiform. Such dentition suggests that their feeding behaviour might be specialised, an expectation which is fully realised.

Members of the genus *Meiacanthus* are unique among fishes in having well-developed toxic buccal glands. Their sabre teeth are grooved, the groove leading to the gland in the dentary bone and acting as a channel for the pale, toxic secretion. All the species of *Meiacanthus* bite when attacked, and

experiments have shown that they are generally unacceptable as prey although naive fish predators may take them into their mouth, only to spit them out quickly. In ecology and behaviour they differ strikingly from most blennies. They inhabit open water and in daytime forage over a wide area in search of small crustaceans in the water column, and tend to hover in one spot then jerk away, to hover again, feeding as they pause.

Their virtual immunity from predators no doubt has a bearing on their behaviour and it is not surprising that several species are brilliantly coloured in life. Various *Meiacanthus* species have close mimics, including unrelated fishes, as well as other sabre-toothed blennies.

The latter include several species of *Plagiotremus* which hover and jump in much the same way as the *Meiacanthus* model. The former feed on larger fishes, especially non-predatory ones, hovering nearby and then launching a lightning attack on the passing fish, usually from the rear. If the prey turns head-on suddenly the attack will be aborted. Their incisor teeth are curved, sharp in the horizontal plane, but flattened in the lateral, are well adapted

to slice skin and scales out of their prey, while the massive fangs provide a purchase as well as breaking the surface tissues. In all the specimens which contained food, Smith-Vaniz found mucus and dermal tissue.

A member of a third genus of sabretoothed blenny, *Aspidontus*, is also an accomplished mimic, but this time of the cleaner wrasse, *Labroides dimidiatus*. *Labroides* is cryptically coloured and tends to hide when approached. *Aspidontus taeniatus* employs its resemblance to the generally unmolested cleaner wrasse to approach naïve prey and attack them, biting off fin rays and associated membranes.

Petrosciurus, the fourth genus of sabretoothed blenny also includes at least two mimics of the venom-fanged *Meiacanthus* species, but most of the 10 species recognised by Smith-Vaniz are retiring and cryptically coloured. They feed on copepods and diatoms and are thus rather unremarkable as

these blennies go. However, for small fish (they rarely grow longer than 60 mm in body length) they are well able to defend themselves, even by snapping at probing fingers.

To complete his account of the nemophine blennies, Smith-Vaniz describes the two species of *Xiphiasia*. True to the nonconformist nature of the tribe, they differ from most blennies. They may attain a length greater than 500 mm, so they are exceptionally large members of the family. They are also semi-pelagic and probably nocturnal, and it seems that they burrow tail first into sand or mud, but their biology is not yet fully studied.

Smith-Vaniz's revision of this tribe of blennies, although primarily a taxonomic treatment, shows them to be animals of striking behavioural and ecological divergence. This group, at least, are far from the dull-coloured, retiring, and modest animals that one generally thinks of as blennies. □

Washington, 1975)). At this stage active transport into the spore compartment can no longer take place so that perhaps exogenous gramicidin is unable to exert its effect.

The requirement for gramicidin at a specific time well before the acquisition of heat resistance suggests that the antibiotic has an indirect effect. More recent work from the same laboratory (Sarkhar, Langley & Paulus *Proc. natn. Acad. Sci. U.S.A.* **74**, 1478; 1977) indicates that gramicidin is a potent and specific inhibitor of transcription *in vitro*. This contrasts with the assumption made hitherto that the antibiotic increases the permeability of cell membranes (Sadoff *Spores* **V**, 157 (American Society for Microbiology, Washington, 1972)). This new work, which made use of a cell-free transcription system devoid of membrane, shows that gramicidin inhibits binding of RNA polymerase to DNA. The inhibition seems quite specific for certain regions of the DNA and this led the authors to suggest that the antibiotic specifically inhibits transcription of particular genes; perhaps those concerned with vegetative functions but not with sporulation. In all work of this kind, however, it is difficult to determine *in vivo* effects of a compound since observations made *in vitro* may be inapplicable to the cells' physiological conditions.

The studies of Paulus and coworkers show that gramicidin is unnecessary for the formation of functional spores though in its absence the spores have some altered properties. This is consistent with the idea that gramicidin acts at a time when it is possibly being produced for a quite different reason—as an antibiotic, for example. Such an interpretation is compatible with the

Antibiotics and bacterial sporulation

from Brian N. Dancer

It has been known for many years that bacteria of the genus *Bacillus* produce antibiotic substances when the cells are beginning endospore formation at the end of growth. These compounds consist of oligopeptides often containing non-protein amino acids and they are not synthesised on ribosomes. They are a heterogeneous group of compounds some of which (such as gramicidin) are surface-active agents whereas others (bacitracin for example) inhibit cell wall synthesis. For some time there has been controversy over their function. Secretion at the end of growth has been seen as a mechanism for inhibiting competitors, and allowing greater growth by the producer organism. Alternatively, antibiotics may be secondary metabolites synthesised to remove accumulated toxic compounds. A third view is that their production at the beginning of sporulation indicates a role in the regulation of the developmental process. If the last were true one would expect that cells deficient in antibiotic synthesis would sporulate abnormally. This hypothesis has recently been tested by Mukherjee and Paulus (*Proc. natn. Acad. Sci. U.S.A.* **74**, 780; 1977) in *Bacillus brevis*, a strain which produces two classes of antibiotic, gramicidins and tyrocidines. The authors were able to select mutants using an ingenious technique developed

by Raetz (*Proc. natn. Acad. Sci. U.S.A.* **72**, 2274; 1975). These mutants are unable to make gramicidin although tyrocidine is still produced. They are able to sporulate but the spores are somewhat less heat resistant than those of the parental strain. The mutants produce reduced amounts of dipicolinic acid—a spore-specific compound.

The heat resistance of the mutant spores can be partially restored by addition of gramicidin at the end of the growth phase (when sporulation begins) but not later. This result indicates that the mutant's behaviour is caused by lack of gramicidin and not by some pleiotropic change affecting both sporulation and antibiotic synthesis. If this interpretation is correct this is the first time that a direct relationship has been clearly shown between these two processes. It is noteworthy that although gramicidin is required early in sporulation its effect is exerted on a very late event. In its absence spores are still produced (albeit slightly defective) indicating that gramicidin is not essential for a major part of the developmental process.

It is possible that the insensitivity to gramicidin after sporulation has begun is associated with an inability to take up the compound. This type of behaviour has been correlated with the closure of the double prespore membrane, resulting in two membranes of opposite orientation (Cooney, Freese & Freese, *Spores* **VI**, 187 (American Society for Microbiology,

A hundred years ago

A WONDERFUL white aquamarine has been found in Perthshire which, when cut, has produced one of the most brilliant gems ever seen. It is said by many competent judges to be equal to her Majesty's celebrated Koh-i-noor, its refraction being very great both by day and night. It is of a pure pellucid liquid white, and is known as the Scotch Koh-i-noor. Its hardness is 8.0, and specific gravity 2.76. Mr. Bryce M. Wright, F.R.G.S., is its possessor.

From *Nature* 16, 7 June, 237; 1877.

Brian Dancer is a research fellow in the Department of Biochemistry in the University of Oxford.

fact that other species of *Bacillus* produce different antibiotics (unrelated chemically and in their mode of action) and yet can still sporulate normally. Although gramicidin must be considered as peculiar to *B. brevis* its properties suggest modifying functions that may apply to antibiotics in other bacteria.

This latest work from Paulus's laboratory, and in particular the technique of mutagenesis, suggests useful methods for exploring the possible function of antibiotics in other strains of *Bacillus*. It may then be possible to decide, species by species, whether these compounds are products associated with prolongation of growth or have a role in the control of bacterial morphogenesis. □

Twenty years after

from P. Pitha

Some 150 scientists attended the Fifth Aharon Katzir-Katchalsky Conference held at the Weizmann Institute of Science, Rehovot, Israel on 2-6 May, 1977. The meeting, organised by the Israel Academy of Sciences and Humanities, was opened by the President of the State of Israel, Dr H. E. Ephraim Katzir, who chaired the first session. It was a welcome, although uncommon, sight to see a head of state participating in a scientific meeting, and could probably only happen in Israel, where the president has always been a scientist.

TWENTY years after its discovery by Isaacs and Lindenmann, how far has interferon fulfilled its clinical potential? Well-controlled clinical studies of the effect of interferon on infection with herpes zoster and hepatitis virus (T. C. Merigan, Stanford University) indicate that interferon treatment started after the onset of infection shortened the time that clinical symptoms of herpes zoster infection were apparent and suppressed virus production in patients chronically infected with hepatitis virus.

In all future trials, however, the supply of interferon may be the rate-limiting step, and a number of groups are actively developing large scale production methods for human interferon. Production of interferon by genetic engineering is also an attractive proposition and several groups have started work on what is undoubtedly

going to be a long and difficult project.

Another major handicap to clinical work has been the lack of purified interferon. Now E. Knight (Du Pont, Delaware) has purified human fibroblast interferon to homogeneity, obtaining a single polypeptide of molecular weight 20,000. However, the major clinical trials have used human leukocyte interferon which is a complex mixture containing distinct components separable by charge and size (W. Stewart, New York), none of them serologically identical with fibroblast interferon. Human lymphoblastoid interferon seems to be a mixture of both leukocyte and fibroblast interferon (J. Vilcek, New York). It is important to determine whether these differences are due to different primary structures, and hence different genes, or to differences in post-translational modification.

Several lines of evidence show that interferon is newly synthesised after induction, and not formed from an inactive precursor. Genetic analysis of human-mouse hybrids continues, although it is still not completely clear whether induction of human interferon requires two chromosomes or only one. Further characterisation of virus-resistant mutant 3T6 cells suggested that constitutive interferon production is involved in this resistance (C. Colby, New York).

It has been shown that interferon production is not regulated at the level of transcription by comparison of the mRNA levels (assayed by injection into *Xenopus* oocytes) with the amounts of interferon produced in human fibroblasts induced by poly (rI)·poly (rC) in normal and superinduction conditions (in which high yields of interferon are produced) (P. Pitha, Johns Hopkins University).

P. Marcus (University of Connecticut, Storrs) reported that a VSV defective interfering particle produced a high yield of interferon at low multiplicity, possibly by formation of a double-stranded RNA within the cell (see *Nature* 266, 815; 1977). This is the best evidence so far that viruses and polynucleotides induce through a common mechanism—formation of double-stranded RNA. However, little is yet known about how the interferon gene(s) is depressed.

Interferon acts by first interacting with the cell membrane, an interaction involving both gangliosides and glycoproteins (H. Ankel, University of Wisconsin, Milwaukee; R. Friedman, National Institutes of Health, Bethesda). Sensitivity to interferon seems to be determined by the receptor located at the cell membrane, however, it is not yet clear whether the species specificity is determined at the same level (C. Chany, Paris; M. Revel, Weizmann

Institute, Rehovot). Work with cell-free systems has made it clear that interferon produces several different effects.

Thus it was shown that in cells of different species interferon treatment induces an increase in the phosphorylation of specific polypeptides. Revel found in interferon-treated cells, the increase of a specific protein kinase which inhibits translation and is cyclic AMP independent. Both the phosphorylation and the translational inhibition mediated by protein kinase are enhanced in the presence of double-stranded RNA. A heat stable, low molecular weight translational inhibitor (probably an analogue of oligo adenylic acid) was found in interferon-treated cells by I. M. Kerr (National Institute of Medical Research, London). For the synthesis of this inhibitor both double-stranded RNA and ATP are required. However, other cellular enzymes such as an endo RNase described in detail by P. Lengyel (Yale University) may be regulated by double-stranded RNA and ATP in interferon-treated cells. The latter two systems, however, were not dependent on the phosphorylation. However, there is as yet no explanation of why the translation of viral mRNA is preferentially inhibited in the intact cell.

In the past, investigation of interferon's antiviral effect has been primarily on the small lytic viruses, and W. Joklik (Duke University, North Carolina) continues his elegant studies on reovirus. However, attention has now shifted to the oncogenic viruses. E. Winocour (Rehovot) and Revel reported that when interferon is added to cells shortly after infection with SV40, it affects translation only. Three papers (Pitha; Friedman; A. Billiau, University of Louvain) on the effect of interferon on MuLV infection showed that in contrast to all other viral systems studied, a late event in virus replication was affected, probably a stage in virus maturation and assembly.

Amounts of purified human interferon similar to those required for the antiviral effect slow cell growth (Knight). Interferon also inhibits delayed type sensitivity, affecting both sensitisation and the expression of the sensitised state (E. De Maeyer, Paris). Interferon also increases the effects of lymphochoriomeningitis virus disease in the newborn mouse, although the mechanism is not known (I. Gresser, Paris). These reports all indicate that interferon may have functions other than its antiviral effect. An important distinction has emerged between type I interferon (virus induced) and type II (induced by antigens and mitogens), and E. Falcoff (Paris) reported that stimulation of B cells produces type I, and of T cells type II interferon. □

Rb/Sr ages and geological setting of ancient dykes in the Sand River area, Limpopo Mobile Belt, South Africa*

Rb/Sr whole-rock ages from two suites of tholeiitic dykes establish a pre-3,600 Myr history for some granodioritic gneisses in the Limpopo Mobile Belt and identify two previously unrecognised magmatic events in the evolution of this region. This has important implications with regard to relationships between the Belt and the adjacent Rhodesian and Kaapvaal Cratons.

WITHIN the Central Zone^{1,2} of the Limpopo Mobile Belt near Messina, South Africa, Bahnmann³ reported rocks which he considered to be basement to an overlying supracrustal sequence. A particularly spectacular exposure of both these units occurs in the valley of the Sand River (Fig. 1), where the basement rocks form a part of a structural unit, possibly a thrust and/or fold nappe, tightly infolded with the cover sequence. The presumed basement rocks, provisionally named the Sand River Gneisses, are comprised mainly of homogeneous peraluminous medium-grained quartz bearing grey gneiss and poorly banded peraluminous medium- to coarse-grained quartz bearing leucocratic gneiss. Detailed mapping (scale 1:100) at Locality 1 (Fig. 1) indicates that the basement gneisses occur as generally steep-dipping, tightly folded interlayered units showing small-scale interference patterns. In addition, both types of gneiss possess an early tectonic fabric and early quartz-feldspathic dykes and veinlets that have been folded at least twice. Rb/Sr whole-rock analyses of both of these gneisses yield an isochron of 3858 ± 116 Myr (2σ) with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.7012 ± 0.0002 (2σ) (B.R. and J.M.B., unpublished). The rocks regarded as being supracrustal to the basement gneisses are predominantly quartzite and iron formation interlayered with garnetiferous metapelatic rocks and with two-pyroxene gneiss, presumably a metavolcanic rock. A conclusive discordant relationship between the basement rocks and the supracrustal sequence has not yet been recognised, although preliminary structural fieldwork (R.E.P.F., in progress) is consistent with such an interpretation. In particular, this work suggests that the early tectonic fabric and early quartz-feldspathic dykes found in the basement gneisses

are not present in the supracrustal rocks. No geochronological data are at present available for these supracrustal rocks.

In addition, as with similar strongly deformed and metamorphosed Archaean terrains in the Outer Hebrides⁴, West Greenland⁵ and Labrador⁶, the basement rocks contain deformed layers of amphibolite, which, in places are clearly discordant with respect to both the gneissic layering and

Fig. 1 Location map of the Sand River area showing the sampling sites. Shaded area denotes outcrops containing basement rocks.

the mineral fabrics in the basement gneisses (Fig. 2) and are, therefore, interpreted as being basic dykes. These dykes post-date the early quartz-feldspathic dykes and veinlets and have been folded and metamorphosed together with the gneisses in conditions of hornblende granulite facies. They have not, as yet, been recognised within the supracrustal rocks. At Locality 2 (Fig. 1), a suite of physically similar, deformed basic dykes show discordant relations with respect to both the grey and the leucocratic gneisses and to other, evidently older, basic dykes (Fig. 3). Therefore, at least two suites of strongly deformed amphibolite dykes are recognised in the basement rocks of the Sand River area, and these are not distinguishable in the field except where juxtaposed and where original discordant relationships are preserved.

Suites of samples of amphibolite, free of younger veinlets (Fig. 3), were carefully selected for Rb/Sr whole-rock iso-

Fig. 3 Photograph of the cross-cutting relationships between the older and younger dykes in the Sand River area. The scale resting on the younger dyke is 10 cm long. Note the deformed felsic veinlets in this dyke, and the large discordant angle between the two dykes.

topic analysis (Table 1) from both the older and younger dykes. These analyses yield isochrons⁹ of 3643 ± 102 Myr (2σ) with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.7014 ± 0.0003 (2σ) for the older suite and of 3128 ± 81 Myr (2σ) for the younger suite (Fig. 4). No clear correlation exists between the K_2O concentrations and the Rb concentrations among these samples (Table 1) and on a plot of K_2O against Rb (Fig. 5), the K_2O concentrations are largely insensitive to changes in Rb concentration for samples from each dyke suite. It is likely, therefore, that each suite underwent some post-intrusive alteration of Rb concentrations. The isochrons, consequently, must reflect the time of such alteration. In view of the older Rb/Sr whole-rock isochron of the surrounding Sand River Gneisses, and the small initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of the dyke suites themselves, these alterations were probably deuteritic in nature and involved the transfer of Rb between the wall rocks and the intruding magma. Such a process has been described by Fratta and Shaw¹⁰ and occurs before crystallisation of the dykes. The isochrons, therefore, very likely also closely approximate the time of intrusion of the dykes.

The initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the older dykes is greater than that normally postulated for the oceanic mantle ~ 3643 Myr ago¹¹⁻¹³. On the other hand, the initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the younger dykes corresponds closely to the mantle value for ~ 3128 Myr ago. It is possible that the higher initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of the older dykes is a consequence of crustal contamination and/or metasomatism ~ 3643 Myr ago. Such hybridisation would necessarily require either the addition of Sr with an $^{87}\text{Sr}/^{86}\text{Sr}$ ratio greater than ~ 0.7014 or the removal of Sr with an $^{87}\text{Sr}/^{86}\text{Sr}$ ratio less than ~ 0.7014 . These initial ratios, however, are also consistent with the possibility that these dykes were derived from distinct sources. If this is true, they support the suggestion by Condie¹³ that a heterogeneous mantle under continental areas formed early in Archaean times and also that a continental-type lithosphere of the type envisaged by Brooks *et al.*^{14,15} may have already been in existence in this region before ~ 3643 Myr ago.

The concept of a heterogeneous subcontinental mantle is further supported by major and trace element compositions of samples from these dykes. As far as major element chemistry is concerned, both generation of dykes are almost identical (Table 2). They have compositions of quartz-normative tholeiites showing significant iron and titanium enrichment, and they contain more iron and titanium than either the Ameralik dykes of West Greenland (13.30%

Twelve samples were collected for study. Of these, five samples were from demonstrably younger dykes, and four from the older dykes. The remaining three samples came from dykes which from a field standpoint, were of uncertain age. Powders of the samples were simultaneously spiked for Rb ($>99.2\%$ ^{87}Rb) and for Sr ($>99.3\%$ ^{86}Sr). ^{87}Rb and ^{86}Sr concentrations are precise to within 0.5% (1σ). The 1σ uncertainty in the $^{87}\text{Rb}/^{86}\text{Sr}$ ratio is $\pm 0.7\%$ while the 1σ uncertainty in the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio is $\pm 0.05\%$. Replicate analyses of the Eimer and Amend standard SrCO_3 yields 0.7080 ± 0.0001 (1σ). The data were tested by both the techniques of York⁷ and Brooks *et al.*⁸ to demonstrate that they scatter less than that amount predicted from experimental uncertainties alone. The ages and initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios were calculated by the technique of York⁸ using $1.39 \times 10^{-11} \text{ yr}^{-1}$ as the decay constant of ^{87}Rb . The K_2O concentrations were determined by X-ray fluorescence spectrometry and are precise to within 0.5% (1σ).

total Fe as Fe_2O_3 ; 0.86% (TiO_2)¹⁸ or the Säglekh dykes of Labrador (14.21% total Fe as Fe_2O_3 ; 1.20% TiO_2)¹⁷. Significantly, however, they have K_2O ($0.8\text{--}0.9\%$) contents greater than those characteristic of oceanic tholeiites ($<0.6\%$ K_2O)¹⁸, but consistent with the contents of K_2O in continental tholeiites (0.9% K_2O)^{19,20}. Furthermore, the older dykes have higher Sr concentrations than do the younger dykes, consistent with the possible existence of a heterogeneous source region.

The Limpopo Mobile Belt has previously been regarded as being largely of late Archaean–early Proterozoic age^{21,22}, and the emplacement of tholeiitic dykes at ~ 3643 Myr and 3128 Myr ago establishes two additional events in the crustal development of the region. Furthermore, the timing of these events supports the possibility that basement rocks to the Limpopo supracrustal rocks are exposed along the Sand River. Some of the supracrustal rocks near Messina are intruded by the Messina Layered Intrusion and are consequently believed to be older than the 3221 ± 48 Myr (2σ) Rb/Sr whole-rock isochron age of this body²³. Some of them are also presumed to be younger than the ~ 3643 Myr age reported here for the older dykes. Therefore, either the ~ 3128 -Myr old dykes should be found in the cover sequence, or the cover sequence exposed along the Sand River is younger than the cover sequence into which the Messina Layered Intrusion was emplaced. In either case, the deformation and high-grade metamorphism

which the rocks of the Limpopo Mobile Belt have undergone, must have occurred more recently than ~ 3128 Myr ago, and this deformation and metamorphism was not of sufficient intensity to obliterate the older isotopic ages.

With the exception of the rocks into which these dykes are intrusive, no other rocks have yet been reported in Southern Africa yielding Rb/Sr whole-rock ages as old as ~ 3643 Myr. Within the Kaapvaal and Rhodesian Cratons, however, granitic rocks yielding errorchrons of between ~ 3600 and ~ 3500 Myr have been reported^{24–26}, and major igneous and/or metamorphic activity occurred from ~ 3520 Myr ago²⁷ up to ~ 2700 Myr ago^{28–31}. Consequently, compared with the ages for the adjoining Rhodesian and Kaapvaal Cratons (Fig. 1), there is nothing particularly unique to the new ages recorded in the Limpopo Mobile Belt. It seems reasonable to assume, therefore, that the Limpopo Mobile Belt is floored by and otherwise contain rocks that are coeval, but not necessarily correlative with, those in the Rhodesian and/or Kaapvaal Craton.

The Lower Onverwacht komatiitic volcanic rocks in the Barberton greenstone belt were deposited sometime ~ 3500 Myr ago^{27,29,32,33} within the span of time from ~ 3643 to ~ 3221 Myr ago during which the Limpopo supracrustal

rocks were presumably deposited. Although no compelling field evidence for a sialic basement to the Barberton greenstone belt has yet been reported, petrogenetic considerations for the evolution of komatiitic magmas suggest that a continental environment existed³⁴. Furthermore, we and others (T. N. Clifford and C. Guerin, personal communication) have observed, on the south-western flank of the Barberton greenstone belt, outcrops of sialic gneisses containing strongly deformed basic dykes. These outcrops are

very similar in aspect to those of the Sand River area, and it now seems likely that detailed structural and isotopic studies, of the type reported in this paper, in the Barberton and Swaziland areas and in particular in the so-called migmatitic-gneiss complex terrains, will confirm the presence of ancient pre-greenstone belt sialic crust³⁵.

Is an early calcium flux necessary to stimulate lymphocytes?

T. R. Hesketh, G. A. Smith, M. D. Houslay, G. B. Warren & J. C. Metcalfe

Department of Biochemistry, Tennis Court Road, Cambridge CB2 1QW, UK

Concentrations of concanavalin A or the calcium ionophore A23187 that are optimal for the transformation of pig or mouse lymphocytes do not normally cause a measurable increase in calcium influx compared with unstimulated cells. If the cells are treated with the mitogens in conditions where a measurable increase in calcium influx occurs, no stimulation of the cells can occur while the flux is maintained. If any early influx of extracellular calcium is necessary for stimulation, then a much smaller increase in the total concentration of cellular calcium than reported previously is sufficient to allow the entry of lymphocytes into the cell cycle.

SEVERAL reports have indicated that mitogens which stimulate the transformation of T lymphocytes cause an increased rate of calcium influx within 1 h (refs 1–6). The magnitude and duration of the calcium fluxes reported for both resting and stimulated lymphocytes, however, vary widely. Thus, Freedman *et al.*⁶ have described a gated calcium flux into mouse T cells stimulated by optimal concentrations of concanavalin (con A) in which a large influx is completed within one minute of the addition of the lectin, after which the gate shuts and the subsequent uptake of calcium is the same as in unstimulated cells. In contrast, Whitney and Sutherland³ have found that there was a very large and continuous increase in Ca²⁺ uptake

Fig. 1 a, Uptake of Ca^{2+} into unwashed pig lymphocytes (10^7 cells ml^{-1}) without FCS at 37°C, at increasing concentrations of ionophore. ○, Control; □, 0.076 μM ; △, 0.19 μM ; ▽, 0.95 μM ; ◇, 1.9 μM . Solid symbols indicate Ca^{2+} taken up by cells pre-incubated with ionophore for 1 h at 37°C before addition of $^{45}Ca^{2+}$. ■, 0.076 μM ; ▲, 0.19 μM . $^{45}CaCl_2$ (0.88 $\mu mol\ Ca^{2+}$ mCi^{-1} ; Amersham) in aqueous solution was added to culture medium to give a final activity of 6 $\mu Ci\ ml^{-1}$. This solution was filtered through a 0.22 μm Millipore filter to remove particulate matter, and aliquots were dispensed into cleaned plastic vials and incubated at 37°C. Filtering the incubation medium improved the reproducibility of calcium uptake levels between different cell preparations. A stock solution of A23187 (19 mM in DMSO) or con A (1 mg ml^{-1} ; Miles-Yeda) was diluted into filtered medium and added to the incubation followed by 50 μl of stock cell suspension to give a final concentration of 10^7 cells ml^{-1} in a total volume of 1.0 ml. Incubations were made under 5% CO_2 in air, with or without continuous stirring in each system¹⁷. Samples of 200 μl were withdrawn and diluted into 10 ml of wash buffer (either 146 mM NaCl, 10 mM Tris, 0.4 mM Ca-EGTA; or 146 mM NaCl, 10 mM phosphate, 0.4 mM Ca-EGTA, pH 7.2; or culture medium) at 3°C and immediately filtered through 2.5-cm Whatman GF/C filters. The cells were further washed with 30 ml of the same wash solution at 3°C within a total dilution and wash time of 4 s, and the filters dried and counted for radioactivity. A wide range of variations in this protocol were examined. The $^{45}Ca^{2+}$ retained was decreased by using larger wash volumes up to 60 ml (<10%); by lengthening the wash time to 45 s at 3°C (<2.5%); and by raising the temperature of the wash medium to 37°C (<45%), whereas removal of EGTA and the addition of 5 mM Ca^{2+} to the wash medium increased the $^{45}Ca^{2+}$ retained by up to 35%. The viability of the cells was unaffected by the filtration and washing procedures, as judged by their retention of $^{51}Cr^{3+}$ and their subsequent transformation by con A. We conclude that the calcium levels measured by the basic protocol represent most or all of the $^{45}Ca^{2+}$ that has been taken up or tightly bound to the cells during incubation at 37°C. In experiments in which transformation of cells from the same preparation was followed after the flux measurements, $^{45}Ca^{2+}$ uptake was measured at the optimal cell concentration for transformation of $3 \times 10^6\ ml^{-1}$. Aliquots of the cells from each incubation for $^{45}Ca^{2+}$ uptake were subsequently shown to be transformed to the same extent as control samples of the same cell preparation set up for transformation (see Fig. 2). **b**, Efflux of Ca^{2+} from unwashed pig lymphocytes loaded with $^{45}Ca^{2+}$ for 30 min at 37°C as for uptake measurements, and concentrated by centrifugation for 30 s at 14,000g (viability unaffected) before diluting into culture medium, with or without ionophore present, to give a final concentration of 10^7 cells ml^{-1} at 37°C. $^{45}Ca^{2+}$ retained in the preloaded cells was measured as for the uptake experiments. ○, Control; □, 0.19 μM ; △, 0.38 μM ; ▽, 1.15 μM .

for at least 24 h in cells stimulated with con A. Since the timing and magnitude of the early events after stimulation are critical in defining the triggering mechanism, and even a requirement for Ca^{2+} in the culture medium during the early stages of stimulation has been questioned⁷⁻¹⁰, we have attempted to determine whether either a gated pulse or a prolonged influx of calcium is obligatory for transformation. We have found that in conditions in which the mitogens cause a measurable increase in calcium influx in pig and mouse lymphocytes, the cells cannot become committed to transform while the influx is maintained. The limit to any calcium influx during the commitment of the cells to subsequent transformation corresponds to an increase in the total cellular concentration of less than 50 $\mu M\ Ca^{2+}$.

Calcium fluxes and transformation stimulated by A23187 and con A

Lymphocytes from pig mesenteric lymph node, or BALB/c mouse spleen were teased into culture medium containing RPMI 1640 (0.43 mM Ca^{2+}), supplemented with 24 mM sodium bicarbonate; 20 mM Tris-HCl; and gentamicin (10 $\mu g\ ml^{-1}$), pH 7.2. These unwashed cells were either used without further treatment, or the cells were washed by centrifugation on to 6.0% Ficoll and 16.7% Triosil, and the interfacial layer of cells centrifuged and resuspended twice in culture medium. For some Ca^{2+} uptake and transformation experiments (see Figs 1 and 2 for methods), 10% heat-inactivated foetal calf serum (FCS; Flow Labs) was also added to the culture medium. The FCS had little effect on DNA synthesis in transformed cells (for example compare Fig. 2a and b).

Calcium influx into unwashed pig lymphocytes in culture medium measured at 30 min in the absence of ionophore was found to be almost constant at 70–80 amol per cell, over the range of cell concentrations from 3×10^6 to 3×10^7 cells ml^{-1} (Fig. 1a, inset). This corresponds to an average cellular calcium concentration of about 0.6–0.7 mM, assuming a cell volume of 120 μm^3 (ref. 11), compared with an extracellular concentration of 0.43 mM. Calcium uptake into the cells at increasing concentrations of ionophore is shown in Fig. 1a. It can be seen that no significant stimulation of calcium uptake can be detected at ionophore concentrations less than 0.3 μM , but increasing the concentration further causes a progressive increase in $^{45}Ca^{2+}$ retained by the cells. Similar calcium uptake experiments were also performed with cells that had been pre-incubated for 1 h at 37°C with ionophore to ensure equilibration before adding $^{45}Ca^{2+}$. The uptake of $^{45}Ca^{2+}$ is unaltered (Fig. 1a), indicating that the absence of a detectable increase in calcium flux below 0.3 μM is not due to slow equilibration of the ionophore with the cells. Ionophore concentrations less than 0.3 μM that have no detectable effect on calcium uptake also have no effect on the efflux profiles from cells preloaded for 30 min with $^{45}Ca^{2+}$ without ionophore present (Fig. 1b). We can conclude that any change in the average cellular calcium concentration is too small to detect against the fluxes occurring in the control cells.

The transformation of the same cell preparations used to measure calcium uptake is shown in Fig. 2a. It is clear that a measurable increase in $^{45}Ca^{2+}$ uptake at 30 min only occurs at concentrations of ionophore that abolish transformation measured as DNA synthesis at 42–48 h. A very similar relationship between calcium uptake and transformation is observed in the presence of FCS (Fig. 2b). An increase in ionophore concentration of about tenfold is required for transformation, presumably because the serum binds a major portion of the ionophore. At the same time, the calcium uptake profile is shifted to higher ionophore concentrations, so that no increase in calcium uptake

Fig. 2 *a*, Uptake of $^{45}\text{Ca}^{2+}$ into unwashed pig lymphocytes in culture medium without FCS after 30 min at 37°C as a function of ionophore concentration, expressed as a ratio to uptake in cells without ionophore. The uptake ratios were the same at 10^7 cells ml^{-1} ($\bullet$) and at 3×10^6 cells ml^{-1} ($\circ$), which was the optimal concentration for transformation measured as DNA synthesis ($\blacktriangle$) in the same cell preparation and medium. Aliquots (200 μl) of the cell suspension at 3×10^6 cells ml^{-1} were incubated with ionophore for 42 h in round-bottomed Cooke Microtitre plates under 5% CO_2 in air, before addition of 0.3 μCi ^3H -thymidine to each well. The cells were collected with a multiple harvester, washed with water and counted for radioactivity. *b*, Same data as in *a* with 10% FCS added to the medium.

is observed at ionophore concentrations that cause transformation.

In the transformation experiments with ionophore, the levels of DNA synthesis were very similar to those obtained with optimal concentrations of con A (Figs 2*a* and 3*a*). Removal of the ionophore after 24 h by centrifugation and washing the cells in fresh medium, approximately doubles the levels of DNA synthesis measured between 42 and 48 h. The highest proportion of pig cells responding to A23187 or con A was approximately 70%, as judged by a count of blast cells at 42 h, similar to the response to ionophore first described by Maino *et al.*¹²

The pattern of response to con A for calcium fluxes and transformation in pig and mouse lymphocytes is shown in Fig. 3*a* and *b*. For pig cells, no significant increase in calcium flux was observed at concentrations of con A between 0.1 and $100 \mu\text{g ml}^{-1}$. The average calcium uptake ratio at con A concentrations that cause significant transformation was 1.04 (s.d. of 0.04 in 26 experiments). The corresponding data for mouse cells shows a significant increase in calcium influx above about $5 \mu\text{g ml}^{-1}$ con A, where transformation is almost completely inhibited. Thus, although the calcium uptake data for con-A-stimulated cells is more variable than the corresponding ionophore

data, for both mitogens at optimal concentrations for transformation there is no significant increase in calcium influx at 30 min.

Commitment to transformation can occur after but not during an early calcium influx

The experiments described strongly suggest that an immediate calcium influx large enough to be measured against the influx into resting cells is not required for transformation, but is apparently inhibitory. We therefore attempted to induce large calcium influxes into the cells to determine whether they would remain viable, and in what conditions they would subsequently transform. Large increases in $^{45}\text{Ca}^{2+}$ uptake at 30 min were induced in pig cells by high concentrations of ionophore (Fig. 1*a*). If the ionophore was then removed by washing, and the cells resuspended in optimal concentrations of ionophore, the viability was unaltered and the cells subsequently transformed normally. Mouse lymphocytes were rapidly killed at ionophore concentrations optimal for pig cell transformation (40% viability after 3 h in $0.3 \mu\text{M}$ A23187) and only small stimulations of DNA synthesis corresponding to about 15% of the maximal stimulation of con A were observed.

In contrast to unwashed pig lymphocytes, the $^{45}\text{Ca}^{2+}$

Fig. 3 *a*, Effect of con A on the uptake of $^{45}\text{Ca}^{2+}$ into pig lymphocytes at 3×10^6 cells ml^{-1} ($\circ$) in culture medium without FCS after 30 min at 37°C expressed as a ratio to uptake cells without con A, and compared with DNA synthesis in the same cell preparation at 42–48 h ($\blacktriangle$). In experiments with con A, both $^{45}\text{Ca}^{2+}$ uptake and transformation were unaffected by washing the cells. *b*, Same data as in *a* for mouse lymphocytes.

Fig. 4 Uptake of $^{45}\text{Ca}^{2+}$ into pig lymphocytes (3×10^6 cells ml^{-1}) either unwashed (●) or washed twice (○) (see text). DNA synthesis at 42–48 h (▲) in the same cell preparation was unaffected by washing the cells.

uptake profile was shifted to lower ionophore concentrations after washing the cells as described previously (Fig. 4). This treatment had no effect on the extent of transformation or the optimal concentration of ionophore required, so that the washed cells showed a significant increase in calcium uptake after 30 min at the ionophore concentrations optimal for transformation. When the time course of calcium uptake was followed by addition of $^{45}\text{Ca}^{2+}$ at increasing intervals after the addition of ionophore and comparing the uptake of $^{45}\text{Ca}^{2+}$ in cells with and without ionophore 30 min later, it was found that the initial increase in $^{45}\text{Ca}^{2+}$ uptake due to the ionophore decreased to the same level as in the control cells after about 4 h (Fig. 5). Subsequently the $^{45}\text{Ca}^{2+}$ uptake was indistinguishable from the control cells for at least 20 h, when the calcium uptake ratio was 1.02 (not shown). By analogy with the effect of FCS on the calcium uptake profile (Fig. 1a and b), it is likely that the large influx of $^{45}\text{Ca}^{2+}$ occurs when any extracellular material from the lymph tissue capable of buffering the ionophore has been depleted by washing, so that more of the ionophore interacts immediately with the cells than in the unwashed preparations. The subsequent decrease in $^{45}\text{Ca}^{2+}$ may result from redistribution, or even metabolism, of the ionophore in the cells. If the increase in $^{45}\text{Ca}^{2+}$ uptake is maintained by further additions of ionophore, no transformation occurs. On the other hand, if the optimal concentration of ionophore is added to the washed cells in ten equal aliquots at 30-min intervals, no significant increase in $^{45}\text{Ca}^{2+}$ uptake is observed, although the cells transform normally as if the ionophore had been added as a single dose.

Calcium fluxes and transformation

Contrary to previous studies, the present results consistently demonstrate that a persistent increase in calcium influx large enough to be detected against the normal levels of calcium exchange in unstimulated lymphocytes is sufficient to abolish the subsequent transformation of the cells. We cannot account comprehensively for this discrepancy, although we would emphasise that to demonstrate the relationship between the calcium flux profile and

transformation (for example, in Figs 2, 3 and 4), it is essential that the measurements are carried out on a single cell preparation using the same mitogen solutions and at optimal cell concentrations for transformation. Small differences between cell preparations and larger differences between batches of mitogens were sufficient to completely obscure the pattern of results. This is particularly important in comparing calcium fluxes with transformations caused by short exposures (for example, 1–5 h) to high ionophore concentrations for which the optimal concentration is significantly higher than for long term stimulations (T.R.H. *et al.*, unpublished). The importance of the experimental conditions is also demonstrated by the facility with which apparently conflicting results can be generated by small changes in the treatment of the cells, where washing pig lymphocytes can induce a significant increase in calcium influx at optimal ionophore concentrations similar to the fluxes described previously. The stimulated influx, however, is transient, and the cells can only become committed to transform after the calcium influx has returned to the unstimulated level.

In most of the previous reports^{1–6,8–10} the increase in Ca^{2+} influx due to ionophore, con A or phytohaemagglutinin can be calculated as ranging between 60 amol per cell and 35×10^3 amol per cell, which if retained in the cell would correspond to an increase in total cellular calcium concentration of 0.5–300 mM. If these large fluxes occur in cells that are to transform, we assume that nearly all of the calcium would have to be pumped out of the cell again or be sequestered in organelles, since 1 mM calcium in the cytoplasm would be sufficient to inhibit glycolysis and protein synthesis, which are both stimulated in transformed cells^{13,14}. It is likely that at supraoptimal concentrations of ionophore, pig lymphocytes are unable to cope with the large and continuous calcium influxes from the medium (0.43 mM Ca^{2+}) and that the cytoplasmic concentration therefore increases to a level which prevents the generation of a mitogenic signal and is eventually cytotoxic. The only report in which the experiments carry the implication that the cell can successfully remove a large calcium influx from the cytoplasm, is the gated calcium pulse described by Freedman *et al.*^{6,9,10}. The kinetic implications of the pulse, which corresponded to an increase in the total cellular concentration of about 2 mM, are important in considering it as a possible mitogenic signal. When the con A and $^{45}\text{Ca}^{2+}$ were added to the mouse lymphocytes at the same time, the increase in the $^{45}\text{Ca}^{2+}$ uptake ratio remained constant after the first minute for at least 20 h (Freedman, M. H., personal communication),

Fig. 5 Uptake of $^{45}\text{Ca}^{2+}$ into unwashed (●) and twice-washed (○) pig lymphocytes, as a function of time. The optimal ionophore concentration for transformation (0.10 μM) was added at start, and $^{45}\text{Ca}^{2+}$ added after increasing time intervals. After 30 min incubation with $^{45}\text{Ca}^{2+}$, the uptake was measured and is expressed as a ratio to uptake in control cells.

whereas the uptake of $^{45}\text{Ca}^{2+}$ added 5 min after the con A, when the gate was shut, was the same as in control cells.

Systematic examination of kinetic models for the calcium fluxes after the gate has shut, in which we have assumed that the calcium entering the cell during the pulse remains accessible for subsequent exchange with the extracellular calcium, has indicated that all of the models require the $^{45}\text{Ca}^{2+}$ uptake ratio to drop from a maximum value after the gate shuts, towards the level of unstimulated cells. Since this is contrary to what has been observed experimentally, we conclude that the gated calcium pulse into the stimulated cells must be deposited immediately at intracellular sites where it is inaccessible for exchange. The subsequent exchange fluxes are then unaffected by the pulse and are the same as in unstimulated cells.

Fig. 6 Inhibition by A23187 of capping (± 1 mM EGTA $\blacksquare$, $\square$) by fluorescein-labelled con A (FITC-con A) on washed pig lymphocytes, compared with the calcium uptake ratio at 30 min for cells from the same preparation ($\circ$). Cells at $3 \times 10^6 \text{ ml}^{-1}$ were incubated in culture medium with ionophore for 20 min at 37°C ; FITC-con A ($200 \mu\text{g ml}^{-1}$) was added, and the cells fixed in 1% paraformaldehyde after a further 10 min at 37°C before examination by fluorescence microscopy. Caps, defined as fluorescent staining restricted to less than half of the cell surface, were present on $30 \pm 5\%$ of the cells, and the results are expressed as a percentage of the number of cells capping in the presence of ionophore. Similar inhibition of capping by the ionophore, was observed with fluorescein-labelled antibody to immunoglobulin which forms caps on more than 90% of the B cells in the absence of ionophore (not shown).

The important features of the gated pulse are that, although it is large, the calcium does not remain free in the cytoplasm where it would be accessible for exchange, and that after the gate shuts, the cell does not have to clear from the cytoplasm a continuous large influx of calcium. Thus the cytoplasmic functions essential for transformation would not be inhibited. Since the pulse is largest at optimal con A concentrations for transformation, is observed in T or B cells only when stimulated with the appropriate mitogens¹⁰, and is modulated by cyclic nucleotides⁶, it has many of the characteristics expected for a mitogenic signal. On the other hand, the absence of a detectable calcium pulse in the present work is unlikely to be due to any insensitivity in the technique used, because the calcium uptake levels in unstimulated cells are similar to those observed by the centrifugation methods, and reproducible increases in the calcium fluxes can be measured at supraoptimal ionophore and con A concentrations that show striking internal consistencies with the transformation data.

If we accept that in some experimental conditions the

cells can transform without requiring an increase in calcium influx that can be measured against the large exchange fluxes occurring in resting lymphocytes, we can set a limit to any increase in the total cell calcium concentration that is obligatory for transformation. For pig lymphocytes at optimal ionophore concentrations, the calcium influx ratio is 1.01 ± 0.06 (33 experiments with FCS) and 1.00 ± 0.08 (22 experiments without FCS). This is equivalent to a change in calcium flux of less than $\pm 6 \text{ amol calcium per cell}$, or a change in the total cellular concentration of less than $50 \mu\text{M}$ calcium. Similar conclusions apply to any induced calcium influx in pig or mouse lymphocytes stimulated by optimal con A concentration. These results raise the question of whether the ionophore or con A act through a calcium flux, and whether calcium is even required in the extracellular medium during the early stages of stimulation, which is at present unclear⁷⁻¹⁰.

There is a further complication in that there is compelling evidence that at least some T-cell subpopulations require macrophages for transformation¹⁴, and it has also been suggested that the ionophore stimulates lymphocytes indirectly by causing the release of soluble factors from macrophages. Although macrophages were not removed from the cell preparations used in the present studies, there is little doubt that the calcium fluxes at supraoptimal ionophore or con A concentrations were too large to be occurring in a small population of cells which were not lymphocytes. We therefore looked for evidence of a direct and immediate action of the ionophore on the plasma membrane of pig lymphocytes, and found that the ionophore inhibits cap formation by fluorescein-labelled con A, at concentrations at which an increased calcium flux can be detected (Fig. 6). This is similar to the observation by Schreiner and Unanue¹⁸ that the ionophore inhibits cap formation by antibody to the immunoglobulin receptor on mouse B lymphocytes, and strongly suggests that the ionophore is also interacting directly with the lymphocytes in the concentration range which causes transformation. Since the inhibition of cap formation requires calcium in the medium (Fig. 6), but not magnesium, we think it is very probable that the ionophore must cause an influx of calcium at optimal concentrations for transformation that is too small to measure by the present technique against the large fluxes in resting cells. The significance of such a small flux as a mitogenic signal and the requirement of extracellular calcium for the early stages of stimulation remain to be determined. The present work does not exclude the possibility that a small increase in cytoplasmic calcium concentration, within the limits described, is a component of the signal that commits the cells to transform.

Endogenous opioid peptides: multiple agonists and receptors

John A. H. Lord, Angela A. Waterfield, John Hughes & Hans W. Kosterlitz

Unit for Research on Addictive Drugs, University of Aberdeen, Marischal College, Aberdeen, UK

Opioid peptides were assayed by inhibition of ^3H -naloxone and ^3H -leu-enkephalin binding in brain homogenates and by depression of contractions of the guinea pig ileum and mouse vas deferens. We conclude that the opioid peptidergic system has agonists of different characteristics which interact with more than one type of receptor.

SOON after the publication¹ of the structures of Met-enkephalin and Leu-enkephalin and the fact that Met-enkephalin is present in β -lipotropin as the sequence 61–65, many papers have appeared which showed that peptides starting with the tyrosine residue 61 of β -lipotropin and having different lengths of amino acid residues interact with the opiate receptors in brain homogenates, guinea pig ileum and mouse vas deferens^{2–7}. The pharmacological properties of these peptides are sufficiently different that the question arises of whether or not they interact with identical receptor populations^{8,9}. Evidence for the presence of more than one species of opiate receptor may be of considerable importance in the analysis of the respective roles of the short- and long-chain opioid peptides. Related to this problem are recent findings which have made it doubtful that the many synthetic and semisynthetic surrogates of morphine in the morphine, morphinan, benzomorphan and phenylpiperidine series of compounds interact with a homogeneous group of receptors^{10–14}. Martin and his colleagues^{12,13} in particular have postulated from behavioural and neurophysiological observations on the chronic spinal dog that there are at least three different opiate receptors: typically morphine-like drugs interact with the μ -receptor whereas certain benzomorphans which do not substitute for morphine in the morphine-dependent monkey but are potent anti-nociceptive agents, for example ketocyclazocine and ethylketocyclazocine, interact with the κ -receptor. In addition, they distinguish the σ -receptor, for which the prototype is N-allylnorcyclazocine.

Differentiation of opioid receptors

Our aim was an analysis of this problem at the cellular level. Receptors of different binding properties present in a mixed receptor population are readily differentiated when antagonists are used which are specific for the different receptors. If such specific antagonists are not available, the agonist activities are assayed simultaneously in several systems. If the rank order of potency varies in parallel in the different assays, then the assay tissues may be assumed to have identical receptors. If, on the other hand, there is no correlation of the rank order of potency in the bioassay systems, the receptor populations are not identical¹⁵.

We used two assays based on pharmacological responses—the depression of the electrically-induced contractions of the guinea pig ileum or its myenteric plexus-longitudinal muscle preparation^{16,17} and of the mouse vas deferens¹⁸. The other two systems are based on the inhibition of binding of labelled ligands in brain homogenates^{19–21}. The primary ligands were ^3H -naloxone (4 Ci mmol^{-1} , 1 nM ;

National Institute on Drug Abuse) and ^3H -leu-enkephalin (45.6 Ci mmol^{-1} , 0.86 nM ; Radiochemical Centre, Amersham). The technique used has already been described⁸; the incubation of the homogenates of guinea pig brain (19 mg per 2 ml Tris buffer pH 7.4 at 0°C , without Na^+) was carried out at 0°C for 150 min to reduce enzymatic inactivation to its minimum. In these conditions maximum specific binding of either ligand was reached after 120 min. Specific binding was the difference between the values obtained in the absence and presence of 50 nM of the potent antagonist (–)2-(3-furylmethyl)-5,9-diethyl-2'-hydroxy-6,7-benzomorphan (Mr 2266 from Dr H. Merz, C. H. Boehringer)²². At the same concentration, the (+) isomer had no significant inhibitory effect on binding. The specific binding was 50–60% of the total binding. There are apparently two binding sites for ^3H -leu-enkephalin (Fig. 1), 18.8 $\pm$ 1.7% of which have a K_D of $0.47\pm0.09\text{ nM}$ and 81.2 $\pm$ 1.7% a K_D of $4.98\pm1.15\text{ nM}$ ($n=4$). Inhibition with cold Leu-enkephalin gave an ID_{50} (concentration for 50% inhibition) of $3.55\pm0.37\text{ nM}$ ($n=18$), a value close to that of the K_D of the binding site of lower affinity. The

Fig. 1 Specific binding of ^3H -leu-enkephalin in a homogenate of guinea pig brain, incubated at 0°C for 150 min. Abscissa, bound ^3H -leu-enkephalin (mol^{14} per 19 mg brain); ordinate, bound/free ^3H -leu-enkephalin.

ratio of binding at 0 and 100 mM Na⁺ is about 10 in our experimental conditions.

Correlation between responses of guinea pig ileum and mouse vas deferens

Investigations carried out over several years on a large number of narcotic analgesic drugs have established a good correlation between the relative agonist potencies in the guinea pig ileum and the mouse vas deferens, on the one hand, and their potencies for human analgesia, on the other^{18,23}. Recently, however, parallel assays of certain benzomorphans which are good anti-nociceptive agents but do not substitute for morphine in the morphine-dependent monkey, showed that these compounds can be distinguished by the fact that in the mouse vas deferens their relative agonist potency referred to normorphine as standard is consistently only 25% of that found in guinea pig ileum (Fig. 2)¹⁴. This finding suggests that these compounds, ketocyclazocines and *N*-dimethylfurylbenzomorphans, interact with a receptor which differs from the μ -receptor and is possibly identical with the κ -receptor of Martin and his colleagues^{12,13}. This view is strongly supported by the fact that in both preparations¹⁴ and in the chronic spinal dog²⁴ these compounds require three to six times more naloxone or naltrexone to reverse their agonist action than is needed for the antagonism of morphine and its surrogates which interact with the μ -receptor (compare with Table 2).

These observations on the heterogeneity of the opiate receptors are strongly reinforced by the behaviour of the endogenous opioid peptides. It is a striking feature that LPH₆₁₋₉₁ (C fragment or β -endorphin) has similar ID₅₀ values in the guinea pig ileum and the mouse vas deferens (Fig. 3). On the other hand, no correlation between the two *in vitro* assay models has been found for the shorter peptides, LPH₆₁₋₇₆ (α -endorphin), Met-enkephalin and Leu-enkephalin are progressively more potent in the mouse vas deferens than in the guinea pig ileum; in the latter preparation Met-enkephalin and β -endorphin are about equipotent but α -endorphin and Leu-enkephalin are less active. In contrast to these findings with the peptides, the mouse vas deferens is much less sensitive to the action of morphine than the guinea pig ileum. The possibility has to be considered that these discrepancies between the two *in vitro* preparations may be due to the fact that α - and β -endorphin are resistant to enzymic degradation whereas the enkephalins are rapidly inactivated by peptidases. It seems, however, that this possibility cannot be the main cause because, in the mouse vas deferens, α - and β -endorphin are the least active peptides and, in the guinea pig ileum, α -endorphin is less potent than Met-enkephalin.

From these observations we conclude that the receptor populations in the guinea pig ileum and mouse vas deferens

Fig. 2 Relative agonist activities of various narcotic analgesic agonists in the mouse vas deferens and guinea pig ileum (normorphine = 1). The compounds fitting the regression line on the right substitute and those fitting the line on the left do not substitute for morphine in the morphine-dependent monkey. Mr 2034, (–)- α -(1*R*,5*R*,9*R*)-5,9-dimethyl-2-(1-tetrahydrofurfuryl)-2'-hydroxy-6,7-benzomorphan (from Dr H. Merz); Mr 1353, (±)- α -5,9-dimethyl-2-(3-methylfurfuryl)-2'-hydroxy-6,7-benzomorphan; Mr 1268, (±)- α -5,9-dimethyl-2-(2-methyl-3-methylfuryl)-2'-hydroxy-6,7-benzomorphan; NIH 8152, (±)- β -2,9-dimethyl-5-*n*-propyl-2'-hydroxy-6,7-benzomorphan (from Dr E. L. May). (Courtesy of Frances M. Leslie).

are not homogeneous and identical. We now show that the opiate receptors present in homogenates of brain are also heterogeneous.

Inhibition of ³H-leu-enkephalin and ³H-naloxone binding in homogenates of guinea pig brain

When the inhibition of ³H-leu-enkephalin is compared to that of ³H-naloxone binding (Fig. 3), it is found that β -endorphin (LPH₆₁₋₉₁) is equipotent in these two systems. α -endorphin (LPH₆₁₋₇₆) is a weaker inhibitor of ³H-leu-enkephalin binding than β -endorphin; this reduction in potency is even more pronounced for the inhibition of ³H-naloxone binding. Met-enkephalin (LPH₆₁₋₆₅) is about equipotent with β -endorphin against ³H-leu-enkephalin binding but a weaker inhibitor of ³H-naloxone binding in confirmation of earlier observations². Leu-enkephalin is somewhat less potent than β -endorphin as an inhibitor of ³H-leu-enkephalin binding; a particularly interesting finding is its weak inhibition of ³H-naloxone binding against which it has an even lower potency than met-enkephalin. In contrast to the peptides, morphine is a much better inhibitor of

Table 1 Relative inhibitory potencies of Met-enkephalin analogues and β -endorphin on the contractions of guinea pig ileum and mouse vas deferens and on the binding of ³H-naloxone and ³H-leu-enkephalin by brain homogenates

Compound	Guinea pig ileum	Mouse vas deferens	Guinea pig ileum-mouse vas deferens	³ H-naloxone	³ H-leu-enkephalin	Naloxone-Leu-enkephalin

†*P* < 0.001.

^3H -naloxone binding than of ^3H -leu-enkephalin binding. The values obtained for naloxone are not included in Fig. 3 and show the same pattern as morphine, the ID_{50} value against ^3H -leu-enkephalin binding being $51 \pm 11 \text{ nM}$ ($n=5$) and against ^3H -naloxone binding $1.8 \pm 0.5 \text{ nM}$ ($n=3$).

Correlation between receptor affinity in the brain and pharmacological potency in the *in vitro* models

Although β -endorphin is equipotent as an inhibitor of ^3H -leu-enkephalin and ^3H -naloxone binding in guinea pig brain and is also equipotent in the guinea pig ileum and the mouse vas deferens, this relationship does not hold for the other naturally occurring opioid peptides. In guinea pig ileum, the potency pattern of the peptides is similar to that found for the inhibition of ^3H -naloxone binding; morphine, however, is more potent than may be expected from the inhibition of ^3H -naloxone binding. It has already been pointed out that, in the mouse vas deferens, α -endorphin, met-enkephalin and Leu-enkephalin are in this order progressively more active than β -endorphin, a pattern fundamentally different from that of inhibition of ^3H -naloxone binding; there is less discrepancy between the order of potency and the values found for the inhibition of ^3H -leu-enkephalin binding. Morphine is a weak inhibitor of ^3H -leu-enkephalin binding which agrees with its weak agonist activity in the mouse vas deferens. It seems, therefore, that in principle, the activity in the guinea pig ileum is better correlated to inhibition of ^3H -naloxone binding than to inhibition of ^3H -leu-enkephalin binding. In contrast, activity in the mouse vas deferens is not correlated to inhibition of ^3H -naloxone binding but seems to have a certain similarity to the pattern of the inhibition of ^3H -leu-enkephalin binding.

This relationship between the binding assays and the *in vitro* preparations is further illustrated when the binding and pharmacological properties of Met-enkephalin are changed by minor modifications of the molecule (Table 1). In the guinea pig ileum, amidation of the carboxyl group of the C-terminal methionine or the introduction of a methyl group in the amino group of the N-terminal tyrosine increases potency a little whereas in the mouse vas deferens activity is decreased, particularly of the latter analogue. The inhibition of ^3H -naloxone binding is about halved by both analogues and that of ^3H -leu-enkephalin reduced by about 70%. A combination of the two modifications yields $N\text{-CH}_3\text{-Tyr-Gly-Gly-Phe-Met-NH}_2$, with characteristics very different from its parent compound: it is almost four times more potent in the guinea pig ileum and only one-third as potent in the mouse vas deferens; it inhibits ^3H -naloxone binding as well as Met-enkephalin but has lost over 90% of its ability to inhibit ^3H -leu-enkephalin binding. Since the potency of Met-enkephalin is about eight times greater in

Fig. 3 The agonist activities of various compounds in the mouse vas deferens and guinea pig ileum and their potencies to inhibit ^3H -leu-enkephalin and ^3H -naloxone binding in homogenates of guinea pig brain ($\text{pH } 7.4$ at 0°C , no Na^+ , 150 min). The numbers on the abscissa indicate the amino acid sequence of β -lipotropin; Leu, leu-enkephalin and Mo, morphine. All peptides are synthetic (61-91, ovine β -endorphin, Dr C. H. Li; 61-76, porcine α -endorphin, Dr R. Guillemin; 61-65, met-enkephalin and leu-enkephalin, Dr B. A. Morgan).

the mouse vas deferens than in the guinea pig ileum, $N\text{-CH}_3\text{-met-enkephalin}$ amide is about 50% more potent in the guinea pig ileum than in the mouse vas deferens; further, since met-enkephalin inhibits ^3H -leu-enkephalin binding about five times more effectively than ^3H -naloxone binding, $N\text{-CH}_3\text{-met-enkephalin}$ amide is three times more potent against ^3H -naloxone than against ^3H -leu-enkephalin. A different picture is obtained when in met-enkephalin glycine² is replaced by the unnatural amino acid D-alanine. Compared with its parent compound, this analogue shows a sixfold increase in potency in both preparations, and is therefore about eight times more potent in the mouse vas deferens than in the guinea pig ileum. Its ability to inhibit ^3H -naloxone binding is halved but there is no reduction in its potency against ^3H -leu-enkephalin which therefore is inhibited about 15 times more than ^3H -naloxone. Thus, $\text{D-Ala}^2\text{-met-enkephalin}$ has a pattern of activity similar to that found for its parent compound, whereas $N\text{-CH}_3\text{-met-enkephalin}$ amide has in its relative, but not in its absolute, potencies acquired a pattern reminiscent of that of morphine. Both compounds show considerable resistance to inactivation by peptidases and after intraventricular or intracerebral administration exhibit antinociceptive activity^{25,26} which therefore does not seem to be closely and exclusively related to their affinity to receptors represented by either naloxone or leucine-enkephalin binding. $\text{D-Ala}^2\text{-met-enkephalin}$ is about equipotent with β -endorphin as an

Table 2 The effectiveness (K_e , nM) of naloxone and Mr 2266 to antagonise the agonist actions of normorphine, enkephalins and benzomorphans without physical dependence capacity

Compound	Naloxone*		Mr 2266†	
	Guinea pig ileum	Mouse vas deferens	Guinea pig ileum	Mouse vas deferens

(±)-Ethylketocyclazocine	14.9 ± 0.9 (4)	11.0 ± 0.6 (3)	2.53 ± 0.60 (4)	4.51 ± 0.54 (6)
Mr 2034	10.4 ± 1.8 (7)	9.1 ± 0.7 (3)	3.34 ± 0.44 (3)	8.4 ± 1.3 (3)

Values are the means $\pm$ s.e.; the number of observations are given in parentheses.

*The values were obtained by a modification¹⁶ of the method of Arunlakshana and Schild²⁸ on segments of ileum. In the myenteric plexus-longitudinal muscle preparation K_e values were obtained by the 'single dose' method¹⁶: normorphine, $1.89 \pm 0.20 \text{ nM}$ (4), (±)-ethylketocyclazocine (Dr S. Archer) $11.9 \pm 1.2 \text{ nM}$ (3) and Mr 2034 $11.9 \pm 1.7 \text{ nM}$ (4).

†Mr 2266 (Dr H. Merz) has some agonist activity so the 'single-dose' method was used on the myenteric plexus-longitudinal muscle preparation and the mouse vas deferens.

antinociceptive agent in the rat²⁷ whereas *N*-CH₃-Met-enkephalin amide is less potent in the cat²⁸.

Differentiation of opioid receptors by action of antagonists

As explained previously, receptors of different binding properties present in a mixed receptor population are best differentiated by antagonists which are specific for the different receptors. The effectiveness of an antagonist against a given agonist is measured by the equilibrium dissociation constant K_e ; the value of this constant is equal to the antagonist concentration which requires a doubling of the agonist concentration to give the same pharmacological response as that obtained in the absence of any antagonist. K_e may also be expressed as its negative logarithm, pA_2 .

In the guinea pig ileum, the enkephalins are as readily antagonised by naloxone as is normorphine (Table 2). In mouse vas deferens, however, about 10 times more naloxone is required for the antagonism of the enkephalins than for that of normorphine. This low antagonist potency of naloxone in the mouse vas deferens seems to hold for all opioid peptides (Table 3), irrespective of whether they are more active in mouse vas deferens than in guinea pig ileum (for example, the enkephalins, α -endorphin and *D*-Ala²-Met-enkephalin), or not (β -endorphin and *N*-CH₃-Met-enkephalin amide).

These observations strongly reinforce the conclusions made from the pharmacological responses to the enkephalins and the endorphins, namely that their action in the mouse vas deferens is on receptors different from those on which morphine and its classical surrogates act. It is important to note that these receptors, which may be called δ -receptors⁸, are not responsible for the action of the enkephalins in guinea pig ileum. Since in this preparation the enkephalins are antagonised by naloxone as readily as morphine, they may be assumed to act on morphine- or μ -receptors.

As far as specific antagonists are concerned, no such antagonist has been found for the putative δ -receptor although the oripavine derivative diprenorphine is relatively more effective than naloxone⁹. The search for an antagonist acting on the putative κ -receptor has been somewhat more successful. In the guinea-pig ileum Mr 2266 is a potent antagonist of compounds acting on μ -receptors (for example, normorphine and the enkephalins) and also of the putative κ -agonists, ethylketocyclazocine and Mr 2034 (Table 2, see Fig. 2 legend for Mr 2034 structure). It seems from these experiments in the guinea pig ileum that, in contrast to naloxone, Mr 2266 acts equally well on μ - and κ -receptors. In the mouse vas deferens, however, Mr 2266

is not more effective as an κ -antagonist than naloxone. This difference between the two preparations is difficult to explain unless one assumes that there are only few κ -receptors in the mouse vas deferens whose relative insensitivity to putative κ -agonists has already been discussed.

Summary of evidence of opioid receptors

Investigation of the pharmacological responses of the guinea pig ileum and the mouse vas deferens to the inhibitory effects of the opioid peptides have led to the view that the receptor populations in the two *in vitro* models are heterogeneous and not identical. In the guinea pig ileum, the peptides interact mainly with the μ -receptor which mediates the action of the classical morphine-like compounds. In the mouse vas deferens, on the other hand, the opioid peptides interact mainly with the putative δ -receptors although they probably also affect the μ -receptors. It would seem likely that the δ -receptors are related to the binding sites in the brain for which ³H-leu-enkephalin has a high affinity while the μ -receptors may be related to the binding sites in the brain and the myenteric plexus of the guinea pig ileum which have a high affinity to ³H-naloxone^{19,29} and to ³H-dihydromorphine^{30,31}.

The guinea pig ileum also has receptors which are probably identical with the κ -receptors first postulated from the results of experiments on the chronic spinal dog^{12,13}; the mouse vas deferens seems to have fewer κ -receptors than the guinea pig ileum. It is not certain whether or not κ -receptors have a role in the action of the endogenous opioid peptides.

In view of the complexity of the opioid receptors, the use of a single assay system can no longer be considered a reliable method for prediction of the pharmacological activity of new opioid compounds, particularly of those with a peptide structure. For such compounds, multiple parallel assays similar to those used in the present investigation may be useful.

Implications of multiple receptors for physiological functions of opioid peptides

One of the most interesting findings has been the fact that β -endorphin inhibits equally well ³H-leu-enkephalin and ³H-naloxone binding, and is also equipotent in the guinea-pig ileum and mouse vas deferens. This observation may be interpreted as indicating that β -endorphin, which is possibly a precursor of other opioid peptides, interacts equally well with several or perhaps all opiate receptors. The shorter peptide, Met-enkephalin, is in several aspects different from its putative parent substance in that it has greater affinity to the binding site of ³H-leu-enkephalin than to that of ³H-naloxone, that it is more potent in the mouse vas deferens than in the guinea pig ileum and, finally, that it is readily inactivated by peptidases. Thus, it seems that Met-enkephalin may be designed for a more specialised function than β -endorphin.

The evidence available at present is insufficient to attempt to allocate different receptors to different physiological functions. We have already pointed out that antinociceptive action does not seem to be exclusively associated with any one receptor. It is, however, apparent that the opioid peptidergic system is of considerable complexity in that several agonists are matched by multiple receptors. These circumstances are similar to those found in the catecholamine system, but whereas in the latter system transmitter action is terminated by neuronal re-uptake, the opioid peptides are rapidly inactivated by enzymatic degradation, as is acetylcholine in the cholinergic system. Is it permissible to compare the neuroendocrine element of the catecholamine system, adrenaline, with the member of the peptidergic system, β -endorphin, which may also have a neuroendocrine function? Adrenaline is present in high

Table 3 Effectiveness of naloxone in antagonising the agonist actions of normorphine and opioid peptides in guinea pig ileum and mouse vas deferens

Agonist	Guinea pig ileum K_e (nM)	Mouse vas deferens K_e (nM)
Normorphine	1.89 ± 0.20 (4)	1.84 ± 0.20 (4)
Tyr-Gly-Gly-Phe	1.73, 1.77	29.2 ± 2.7 (4)
Met-enkephalin	2.45 ± 0.26 (4)	22.6 ± 0.5 (4)
α -Endorphin (61-76)	1.56 ± 0.15 (4)	22.5 ± 2.9 (4)
β -Endorphin (61-91)	2.86 ± 0.42 (5)	21.7 ± 1.2 (3)
<i>N</i> -CH ₃ -Met-enkephalin	2.07 ± 0.08 (4)	15.6 ± 3.8 (4)
<i>N</i> -CH ₃ -Met-enkephalin amide		16.6 ± 2.6 (4)
<i>D</i> -Ala ² -Met-enkephalin	2.55 ± 0.20 (4)	22.4 ± 2.7 (4)

K_e values were determined by a modification¹⁶ of the method of Arunlakshana and Schild²⁸ or the 'single dose' method¹⁶ and are the means ± s.e.; the number of observations are given in parentheses. Tyr-Gly-Gly-Phe was provided by Dr B. A. Morgan.

concentration in the adrenal medulla and β -endorphin and α -endorphin are found in the intermediate and anterior lobes of the pituitary gland, also in high concentrations³². Adrenaline is essential for the fight and flight reaction. β -Endorphin may be of similar importance: could the often reported lack of pain perception on the battlefield or the reduced pain experienced during childbirth be explained on this basis? In contrast, the other components of the two systems, noradrenaline and dopamine on the one hand, and Met-enkephalin and Leu-enkephalin on the other, are present in lower concentrations in widely-spread areas of the central and autonomic nervous systems^{33,34}. Immunohistochemical studies show that Met-enkephalin and Leu-enkephalin are widely distributed in neuronal fibres and terminals of the central nervous system of the rat^{35,36}. These findings and the rapid inactivation of the enkephalins are compatible with the role of neuromodulator or neurotransmitter suggested for them^{34,37}. If this concept is correct, it would follow that the enkephalins would subserve transmission of a rapid and more or less transient character while the longer-chain peptides, particularly β -endorphin would mediate neuronal and possible endocrine changes of a more lasting nature.

letters to nature

Comments on the optical and radio detection of black hole explosions

It has recently been suggested¹ that it may be easier to detect the explosions of miniholes by the radio and optical pulses produced by the interaction of the emitted particles with the interstellar magnetic fields, than by the direct detection of the high energy γ rays².

We concern ourselves here first with the possibilities in the optical band. In the several attempts in recent years to detect fast transient phenomena in the visible band^{3–5}, including searches for X-ray bursts by the upper air atmospheric fluorescence technique^{6,7} the time constants have covered the region $\sim 100 \mu\text{s}$ to 10 s. Most of these experiments have been bedevilled by interference of one form or another, both man-made and natural.

The radiation mechanism proposed by Rees¹ is unique in that its timescale is far shorter than that for any other known phenomenon in the optical band. The pulse width or at least the rise time, for emission at a characteristic wavelength λ , on one of the models discussed, will be $\sim (\lambda/c)$ or $\sim 10^{-15}$ s. The shock front will be broadened by dispersion, both in the interstellar plasma and in the terrestrial atmosphere. The smearing due to the former, normally considered insignificant in the optical region, amounts to $\sim 5 \times 10^{-13}$ s over the band $\lambda = 400\text{--}600$ nm, if we accept a typical but arbitrarily chosen value of $DM = \int n_e dl \sim 50$ electrons cm^{-3} pc. The atmospheric dispersion is $\sim 2 \times 10^{-10}$ s for a scale height of 7 km and a

variance of 2.5% in $(n-1)$ over the same bandwidth. In either case, however, the timescales are much shorter than the response times of existing detectors, ~ 1 ns for small phototubes and ~ 10 ns for larger ones.

An optical search for shocks from minihole explosions has two practical advantages over radio. First, the fractional bandwidth which can be used is large, ~ 0.4 , and second, in the optical band, the only known sources of pulses on these timescales arise from Cerenkov flashes produced by extensive cosmic-ray showers⁸. This contrasts markedly with the situation at radio frequencies in which bandwidth-limited interference pulses are always observed, though in this case dispersion can be used to advantage for a celestial source.

If S_0 is the source strength in the optical band and we demand that the detected signal, on a timescale τ , shall exceed the threshold sensitivity set by the night-sky background noise, the distance d at which a single black hole explosion would be detected by a phototube of given quantum efficiency, with a mirror of effective area A and acceptance cone Ω , is

$$d = (S_0/4\pi)^{0.5} \text{const} (A^{0.25} \Omega^{-0.25}) \quad (1)$$

Since, however, the locations of the explosions are unknown, we must assume they are uniformly distributed and occur randomly over time. In this case, the observable volume will be

$$V = (\Omega d^3/3) = \text{const}' (A^{0.75} \Omega^{+0.25}) \quad (2)$$

From this we conclude that we require a flux collector

rather than a telescope, one with the largest collecting area and acceptance cone. The installations which have been used so extensively in high energy γ -ray astronomy⁹ therefore fulfil the requirements. In this technique, based on the Cerenkov effect of extensive cosmic-ray showers in the atmosphere⁸ resolving times τ of ~ 10 ns are in regular use and A and Ω are both large. For the large 10-m optical reflector at Mount Hopkins¹⁰, $A = 60 \text{ m}^2$ and $\Omega = 1.5 \times 10^{-4} \text{ sr}$ (ref. 7, p336). It is this flux collector which has already been used¹¹ to search for the γ -ray bursts originally predicted from minihole explosions².

The first example suggested in ref. 1, in which 10^{18} J might be emitted optically, in the case for $\gamma \sim 300$, gives an unfavourable prediction since the radiation from the fireball will be incoherent, and the duration of the pulse $\sim 0.1 \text{ s}$, just the time domain in which the interference problems are serious. It has, however, more recently been pointed out to us (M. J. Rees, personal communication) that the particle physics may be such that $E_{\text{opt}} \sim 10^{23} \text{ J}$, $\gamma \sim 10^7$ and hence that the radiation would then be coherent. In this case the prospects look much better. Taking the sensitivity of the 10-m reflector to be 5 photon m^{-2} (ref. 7, p.336) an explosion of 10^{23} J at $\lambda \sim 450 \text{ nm}$, for $\tau \sim 10 \text{ ns}$, would be detectable out to $d \sim 2 \text{ kpc}$ for which, from equation (2), $V \sim 4 \times 10^8 (\text{pc})^3$.

A multiplicity of spaced flux collectors would, however, be required, to suppress the chance-rate arising from Cerenkov flashes¹¹ from extensive cosmic-ray showers and other local phenomena. The intrinsic threshold detection rate for pbh explosions of this type would be $\sim 4.10^{-5} \text{ yr}^{-1} (\text{pc})^{-3}$ for the above volume and an observing time of $\sim 500 \text{ h}$. To achieve such a limit however, T. C. Weekes (personal communication) has pointed out that about five stations would be required, for an air-shower rate $\sim 10 \text{ s}^{-1}$ at each station and a coincidence resolving time $\sim 1 \text{ ms}$.

Turning now to the question of detecting radio bursts from pbh explosions, the situation is different, in that certain limits can already be set from experiments in other areas. In the radio region, the relationship between A and Ω is fixed, by the coherence properties of antennas.

If the energy emitted by a minihole explosion in unit bandwidth in the radio region is S_R , then the maximum distance for the detection of such an explosion is given by $d_{\text{max}} = (S_R/4\pi\epsilon_R)^{0.5}$ where ϵ_R is the energy threshold per unit area per unit bandwidth of an actual receiver system. For a single radio receiving system working at a specified frequency, $A\Omega$ is a constant, and $\epsilon_R \propto A^{-1}$, so that in the radio case, the corresponding expression to (2) is

$$V = \text{const}'' A^{0.5} \quad (3)$$

The achievable limits on the number of miniholes producing radio pulses is then proportional to $(A^{0.5}T)^{-1}$ where T is the total observing time of the experiment. The many radio experiments quoted in the literature can be divided broadly in two classes; firstly those involving small wide field of view antennas at low frequencies run for long periods of time, and secondly, those involving larger directional antennas at higher frequencies usually run for shorter periods. The duration of the emitted pulse is not a dominant consideration in most of the experiments as, provided the pulse duration, to include broadening by dispersion, is less than the system integration time, it is only the total energy in the pulse that determines the threshold level.

The characteristic frequency ν_c for the radio emission estimated by Rees, varies as a high power of γ_f ($\sim 2 \times 10^{16} \text{ g } M_{\text{crit}}^{-1}$); for $\gamma = 10^5$, $\nu_c \sim 3 \text{ GHz}$. Without knowing the values of γ , the optimum frequency cannot be selected in advance. We have calculated therefore the upper limits on the rates of such explosions, R , (99.9% confidence level) for two representative systems; one in each of the above classes (Table 1). In comparing these limits with those obtained in the γ -ray searches¹¹ it must be borne in mind that the radio and optical emission predicted by Rees is critically sensitive to

Table 1 Upper limits on the rates of explosions for two representative systems

System	ν (MHz)	$\delta\nu$ (MHz)	Antenna	Ω (sr)	Duration of experiment (h)	R ($\text{pc}^{-3}\text{yr}^{-1}$)
Small wide field of view antennas run for long periods ¹²	151	1	Dipoles	~ 1.3	3620	7×10^{-4}
Larger directional antenna run at a higher frequency for shorter periods ¹³	1665	15	25.6m dish	2.2×10^{-4}	28	0.1

the value of γ_f , which depends on the particle physics assumed.

We would like to thank Professors M. J. Rees and N. A. Porter for the opportunity to discuss this work, and the Dublin authors acknowledge the assistance of AERE Harwell through an extramural research grant.

Optical pulses from primordial black hole explosions

REES¹ has pointed out recently that explosions of small black holes² could be detected by the radio or optical emission from an expanding relativistic shock wave interacting with the ambient magnetic field. The frequency of the radiation is determined by the value of a parameter $\gamma_f = (2 \times 10^{16} \text{ g}/M_{\text{crit}})$, where M_{crit} is the mass at which the black hole explodes. Jelley *et al.*³ have considered the optical emission and the radio emission which will occur for $\gamma_f \sim 10^5$, and shown that upper limits can be set for the rate of explosions, from previous measurements at 150 and 1,700 MHz.

For a lower value of γ_f , corresponding to the nuclear model of Hagedorn⁴, optical emission will be produced, but it will be incoherent, and the fraction of the total energy appearing is small. A limit has been set for γ rays for this model, using the atmospheric Cerenkov technique, by Porter and Weekes⁵. As Jelley *et al.* have pointed out, Cerenkov systems are suitable also for detecting fast optical pulses. For a γ_f value of 10^7 , 10^{30} erg of optical radiation

are predicted by ref. 1. This would correspond to a nuclear model at the opposite extreme from the Hagedorn model, and it is not clear whether the black hole explosion could occur in a sufficiently short time to give the required shock front.

If such an optical pulse is produced, however, the measurements made in ref. 5 can be used to provide an upper limit for the explosion rate. The optical sensitivity of the detectors was $370 \text{ photons m}^{-2}$ corresponding to $1.6 \times 10^{-13} \text{ erg cm}^{-2}$. The maximum distance for detection is then $r = E^{1/2}/2\pi^{1/2}F^{1/2}$, where E is the total energy produced and F the optical sensitivity. With $E = 10^{30} \text{ erg}$, r is $7 \times 10^{20} \text{ cm}$, or 230 pc. With the solid angle of $4 \times 10^{-3} \text{ sr}$ available, this gives a sensitive volume of $1.5 \times 10^4 \text{ pc}^3$.

The observed one event in 15.3 h of observation³, which is compatible with random expectation, corresponds to an upper limit of 6.8 events at the 99% confidence level. This yields an upper limit of $3.9 \times 10^3 \text{ events yr}^{-1}$ and hence an upper limit for the explosion rate of $0.3 \text{ events pc}^{-3} \text{ yr}^{-1}$. The limit found for γ rays was of the same order, but this was, of course, for the Hagedorn or Composite Particle model, in which 10^{30} erg are released at the explosion.

The sensitivity of this experiment could be improved by the use of a larger array of separated detectors, to reduce the chance rate, and a longer running time. In order to reach the sensitivity quoted by Jelley *et al.*, however, at least four very large optical reflectors each of aperture greater than 10 m and separated by more than 10 km, would be required. This calculation assumes a coincidence resolving time of 10^{-4} s and a running time of 500 h.

The authors would like to thank Professor M. J. Rees for communication of results before publication; Dr G. A. Baird, Dr J. V. Jelley and Dr E. O'Mongain for helpful discussions; the Smithsonian Research Foundation and the National Science Council of Ireland for support.

Neutrino angular momentum losses in stellar collapse

WE know from observation that even the most rapidly rotating neutron stars—those of the Crab and Vela—are slow rotators, in the sense that their angular momentum is of negligible structural importance. In fact, at least for these pulsars, estimates based on their current slowdown rates indicate their rotation frequencies at birth were probably only a few times higher than the present ones¹, even though the main sequence progenitors probably had much more angular momentum per unit mass. The purpose of the present note is to examine the degree to which one can attribute such a decrease in the angular momentum per unit mass to neutrino radiation emitted during the formation of the neutron star from the collapse of a sufficiently massive stellar core.

According to the current theory, pulsars are presumably neutron stars which originate from the collapse of the cores of sufficiently massive stars ($M \geq 7M_{\odot}$) (ref. 2). After thermo-

nuclear burning has stopped, such stellar cores reach a state of very high density and temperature, so that the electron chemical potential is high enough to favour electron absorption on to protons ($e^- + p \rightarrow n + \nu_e$) over the reverse reaction (β decay). Electrons are thus eliminated, and so their contribution to the pressure decreases, causing the core to collapse. At the same time, vast amounts of neutrinos are produced by the inverse β decay and other thermal processes, taking up all the gain in gravitational energy arising from the collapse. The core finally settles down at densities of the order of $10^{14} - 10^{15} \text{ g cm}^{-3}$, it is then supported by nuclear degeneracy. One expects the stellar core to be rotating, increasing its angular velocity while collapsing by conserving angular momentum. The neutrinos leaving the core are emitted from a surface shell, approximately one mean free path thick. These neutrinos were initially produced throughout the core and not necessarily near its surface. If the rotation of the core is uniform, neutrinos of low angular momentum regions interact before escaping with the high angular momentum material of the surface. The result of such an interaction will be the neutrinos will gain angular momentum and so the angular momentum per unit mass of the escaping core will fall.

Let us consider a simple model, which allows analytic calculations and includes the general features of the actual situation, in order to estimate the effect neutrinos can have on the rotation of such a collapsing core. Consider a homogeneous spherically symmetric and uniformly rotating core, collapsing from density $\sim 10^{12} \text{ g cm}^{-3}$ to $10^{15} \text{ g cm}^{-3}$, and neutrinos take away all the gain in potential energy arising from the collapse.

In this core consider a spherical shell between r and $r+l$ (Fig. 1) ($r \gg l$, $l \approx$ neutrino mean free path). Let $E(r)$ be the

Fig. 1 Section through a burnt-out stellar core.

rate at which energy in the form of neutrinos is leaving the mass inside radius r . These neutrinos are emitted isotropically in the fluid's rest frame. Owing to the relativistic 'head light effect'³ from an inertial frame emission will seem to take place preferentially along the direction of rotation, resulting in a net angular momentum loss. This loss is further enhanced by a Doppler shift in the energy of the forward-against the backward-

emitted neutrinos. It is then easy to show that the part of the core inside radius r is losing angular momentum at a rate

$$\dot{J}(r) = -\frac{7}{9} \frac{\dot{E}(r)}{c^2} \omega r^2 \quad (1)$$

where ω is the angular velocity of rotation. These neutrinos and the corresponding angular momentum, are of course deposited in the shell between r and $r+l$, and then re-emitted at radius $r+l$, taking away angular momentum at a rate $\dot{J}(r+l)$. The net effect on the shell, therefore, will be to lose angular momentum at a rate

$$\dot{J}(r) - \dot{J}(r+l) = -\frac{7}{9} \frac{\dot{E}(r)}{c^2} 2\omega r l + O\left(\frac{l}{r}\right)^2 \quad (2)$$

Summing up the angular momentum loss rate over all shells, the total angular momentum loss rate is found to be

$$\dot{J}(R) = -\frac{1}{3} \frac{7}{9} \frac{\dot{E}(R)}{c^2} \omega R^2 \quad (3)$$

where R is the core radius and $\dot{E}(R)$ the total energy loss rate, which for the homogeneous sphere assumed in our case is

$$\dot{E}(R) = -\frac{3GM^2}{5R^2} \dot{R}$$

where M is the mass of the core.

The evolution now of angular velocity ω with R as the core collapses is easy to be followed by the equation

$$I\dot{\omega} + \dot{I}\omega = \dot{J} \quad (4)$$

where $I = 2/5 MR^2$, is the moment of inertia of the collapsing core. Straightforward integration of equation (4) gives

$$\omega = \omega_0 \left(\frac{R_0}{R}\right)^2 \exp\left[-\frac{1}{2} \frac{7}{9} \frac{GM}{c^2 R_0} \left(\frac{R_0}{R} - 1\right)\right] \quad (5)$$

(The subscript zero denotes the initial values of the corresponding quantities.)

The loss of neutrino angular momentum affects only the value of the exponential factor in equation (5) (see Fig. 2). Since the mass of the collapsing core and the ratio of its initial to final radius determine the total energy available to neutrinos for slowdown, it is not surprising that the neutrino angular momentum depends on them.

If we substitute realistic values for these quantities we can estimate how big the effect should be. For $R_0/R = 10$ and $M = 1.5M_\odot$ we find the value of the exponential factor to be 0.91. If we take $M = 2.5M_\odot$, which is close to the highest non-rotating neutron star mass allowed by an asymptotic free quark equation of state (Kislinger & Morley, personal communication), then its value is reduced to 0.88. So neutrinos seem to decrease ω from its expected value $\omega_0 (R_0/R)^2$ by 9% and 12% respectively for the two masses considered here. At even higher masses cores collapse to black holes. The magnitude of the effect then reaches a maximum ($\sim 18\%$ decrease), independent of the mass of the collapsing core, corresponding to $R = r_s = 2GM/c^2$ (the Schwarzschild radius) and $R_0 \rightarrow \infty$.

We have shown that neutrinos tend to slow down the rotation of a collapsing stellar core by carrying away part of its angular momentum. The effect seems to be present in all rotating collapsing cores, but does not completely account for the slow rotation of the compact supernova remnants (pulsars). But the angular momentum taken away by neutrinos and deposited in

Fig. 2 The kinetic energy of the collapsing core T , measured at any instant in units of its value if no angular momentum losses are present T_0 , as a function of the core radius. *a*, For $M = 1.5M_\odot$ and $R/R_0 = 0.1$; *b* for $M = 2.5M_\odot$ and $R/R_0 = 0.10$; *c*, collapse to a black hole with $r_s/R_0 = 0.1$. The arrow indicates the (minimum) value of the ratio T/T_0 in the case that $r_s/R_0 \rightarrow 0$.

the expanding envelope may have some observational effects (that is, axial rather than spherical symmetry of the ejecta) or may help the explosion. Generalisation also of the above spherically symmetric treatment to sufficiently slowly rotating McLaurin spheroids gives essentially the same results. If we do not assume that rotation is uniform, the slowdown effect is smaller. In such a case neutrinos will act as sort of radiative viscosity smoothing out inequalities in the angular velocity.

I thank Professor D. N. Schramm for stimulating discussions and critical reading of the manuscript; also N. Lebovitz, P. J. Witta, S. Margolis, D. L. Tubbs for discussion; M. Kislinger P. Morely are thanked for pre-publication results. This work was supported in part by the NSF.

Small scale auroral absorption events associated with substorms

We describe the first results obtained from a new facility designed to study auroral absorption events exhibiting small scale spatial structure and rapid temporal variations. The absorption is measured by means of a modern solid-state riometer with high time resolution¹ and the spatial resolution is obtained using a narrow-beam antenna with 64 elements. The most striking observations made so far involve intense, short-lived 'spikes' of absorption associated with the onsets of auroral substorms. These spikes, which seem to be of small spatial scale, are probably related to the sudden ionospheric absorption (SIA or SAI) events reported by previous workers²⁻⁵ and perhaps to the 'spikes' of intense energetic electron precipitation observed from polar-orbiting satellites⁶⁻¹¹. Five such spikes were observed during November and December 1975.

The antenna array is constructed of elements made of coaxial cable (RG-62) with the inner and outer conductors interchanged at half-wavelength intervals¹². Eight such elements, each equivalent to eight half-wave dipoles, are mounted with a half wavelength between adjacent elements and a quarter wavelength above a ground plane. The antenna was first set up in Lindau and its radiation pattern determined by flying a portable transmitter through it. The predicted and observed patterns are in reasonably good agreement with $\sim 16^\circ$ between half-power points and with the side-lobes suppressed about 10 dB below the main beam (see Fig. 1). A similar array was erected in Ramfjord ($L \sim 6.2$) near Tromsø in northern Norway at the end of 1975. The riometer, which operates at a frequency of 51.4 MHz, has a band width of 150 kHz and a time constant of 0.25 s for both increasing and decreasing signal intensities¹.

Fig. 1 Power polar diagram of the riometer antenna. The full-drawn curve represents the calculated pattern, while the two other curves are results of measurements of the directional variation of the antenna gain. The transmitting antenna used in these measurements was a crossed Herizian dipole taped on to the underside of the non-metallic body of an aircraft.

An example of one of the more impressive spikes observed during the first few months of operation of the system is shown in Fig. 2a. The absorption is shown as the equivalent absorption at 30 MHz assuming that the absorption varies inversely as the square of the frequency. The absorption observed simultaneously from a broad-beam 30-MHz riometer is also shown for comparison. The spike has a duration of approximately 1 min and the maximum absorption at 51.4 MHz is ~ 8 dB, corresponding to ~ 25 dB at 30 MHz. The maximum absorption measured by the broad-beam 30-MHz system was significantly smaller (~ 7.5 dB), which suggests that at the time the absorbing region did not completely fill the beam. Following the spike, there is a good correspondence between the two sets of observations. This indicates that the region of electron density enhancement in the D layer which produced the absorption had a spatial scale comparable with, or larger than, the field of view of the antennas and that the bulk of the absorption occurs at an altitude where the signal frequency is much larger than the electron-neutral collision frequency (that is, $\gtrsim 60$ km).

The absorption spike, which occurred at ~ 1750 UT on 3 November 1975, is coincident with the very sharp onset of a negative bay ($\sim 680\gamma$, Fig. 2b) and a rapid declination variation (~ 150 arc s), both of which had time scales

Fig. 2 a, An example of a very intense spike in ionospheric absorption occurring at Ramfjord at ~ 1750 UT on 3 November 1975. The circle and the stars indicate absorption measured using a broad-beam 30-MHz antenna (P. Stauning, personal communication). The absorption measured directly is marked with a circle, while absorption measurements corrected for zenith angle effects are marked with a star. This correction is made with the assumption that the sky temperature and absorption are homogeneous. b, Storm magnetogram from Tromsø showing H component of magnetic field (A. Brekke, personal communication). The absorption event occurred during the negative bay. c, ATS-6 36-keV electron measurements (C. E. McIlwain, personal communication). The counting rate started to increase about 1 min before the absorption, which may indicate that the magnetic conjugate point to ATS-6 was located south of Ramfjord before the absorption event.

of the order of 1 min. The substorm onset was observed simultaneously by energetic particle detectors on the geostationary Earth satellite ATS-6, which at the time has its geomagnetic conjugate point located 0.9° east and 1.0° south of our ground station in Ramfjord¹³. As observed at the satellite, the substorm was characterised by an increase by a factor of ~ 200 in the intensity of 36 keV electrons which took place with a timescale of the order of 1 min at 1750 UT. The electron intensity was observed to decay by a factor of about 10 during the next few minutes, so that in effect an electron spike was observed with a time duration of the order of 1 min. The 36-keV electron count rate is shown on a linear scale in Fig. 2c for comparison with the absorption measurements.

It is not completely clear how these observations can be interpreted in the absence of other evidence. One possibility, however, is that an absorbing region, spatially restricted in one direction but extended in the other, passed rapidly across the point of observation. If we assume that the vertical pencil beam absorption has the form $A(x) = A_0 \exp(-x^2/2x_0^2)$, where x is the horizontal distance from the line of maximum absorption, then, using both narrow- and broad-beam absorption measurements, one finds that the width of the absorbing region ($2x_0$) must have been about 50 km or 0.5 degrees of latitude if the absorption is assumed to occur at an altitude of ~ 80 km. Simultaneous broad-beam observations at 30 MHz and 40 MHz are consistent with this interpretation (P. Stauning, personal communication). The spatial scale we have deduced is consistent with the latitudinal width of energetic particle spikes observed by low-altitude satellites⁸⁻¹¹. Since the absorbing region must pass through the riometer antenna beam and intersect the conjugate point to ATS-6 within a time span of ~ 1 min at the most, the horizontal speed of the absorbing region must be quite considerable (that is, ~ 1 – 10 km

s^{-1}). This speed is similar to that of the poleward surge of auroral substorms¹⁴. Unfortunately we are unable to determine from the available all-sky camera records (one picture every 5 min) whether or not an arc-like structure passed rapidly over our observation point at the time in question.

An alternative possibility is that the effects we have observed are largely due to variations in the energy spectra and pitch-angle distributions of precipitating electrons associated with the substorm. Indeed, intense spikes of energetic electrons with pitch-angles almost parallel to the local magnetic field direction have recently been observed by the polar orbiting satellite OGO-6 (ref. 16). If, however, the bulk of the electrons involved have energies which are not greatly in excess of ~ 400 keV it is difficult to explain the difference between the relatively intense absorption observed at 51.4 MHz in comparison with that at 30 MHz. Of course some combination of these suggestions may be required to give a fully satisfactory explanation of the observations.

The absorption spikes have so far only been observed during the evening hours (1900–2200 CMLT). This result is consistent with statistical studies of riometer absorption¹⁵, which reveal one maximum of occurrence in the evening hours and with the pattern of occurrence of particle spikes observed by satellites¹¹. Auroral observations made from ISIS-2 also suggest that the initial brightening of substorms occurs more frequently in the late evening sector than in the midnight sector¹⁴.

We plan to extend the scope of these observations by making suitable changes in the system. A second broad-beam 51.4-MHz system is being set up in order that a definitive distinction can be made between spectral and spatial effects. We also intend to make photometer and television observations to see whether or not similar phenomena occur in the optical emissions. Simultaneous observations will be made using the VHF radar system 'STARE' which was recently put into operation¹⁷, and correlations will be made with energetic particle observations from the satellite GEOS.

A proposed cadmium-selenium film-electrolyte Schottky barrier solar cell

ECONOMIC analyses of photovoltaic solar cells show that a considerable manufacturing cost reduction will be required before such devices can give a positive contribution to the World's energy needs. To this end, efforts have been made to divert some research work from the high-quality single-crystal

technology, which supports the present commercial solar cells, to alternative systems incorporating less pure, polycrystalline materials, deposited as thin layers to avoid wastage of expensive elements. This letter describes the operation of a novel system which may be constructed from relatively inexpensive materials, yet which converts solar radiation into electrical energy with an efficiency greater than some similar systems previously reported.

Considering the replacement of single crystals by polycrystalline materials, we find that grain boundaries can contribute to the following major limitations to the ultimate cell efficiency: first, recombination of photogenerated electron-hole pairs occurs if the optical absorption distance exceeds the minority carrier diffusion length, which is limited by the grain size; secondly, the formation of a well-defined p-n junction is complicated because of preferential adsorption of dopants at grain boundaries. The former may be avoided by the use of direct band-gap semiconductors, and the latter by replacement of the p-n junction with a Schottky barrier.

A recent development in Schottky barrier cells was the semiconductor-electrolyte liquid junction in which the usual metallic contact was replaced by a suitable electrolyte solution¹. Ellis *et al.*² showed the systems CdS (single crystal)-Na₂S_n solution and CdSe (single crystal)-Na₂S_n solution to be stable under illumination, in contrast to previous systems which had degraded by photochemical reactions. A similar electrolyte was seen to preserve semiconductor stability when Miller *et al.*³ constructed solar cells using anodically prepared films of CdS and Bi₂S₃. The efficiency of the single crystal CdS cell was limited by the high band-gap of CdS whereas CdSe gave a remarkable efficiency when used in etched single crystal form. Anodic Bi₂S₃, however, was found to be less efficient than anodic CdS despite its favourable band-gap. Since CdSe has been shown to be more efficient than CdS in single crystal form, it was thought that a comparison of the respective polycrystalline films would be informative.

Anodic films of CdS were prepared in constant current conditions. The Cd anode was kept in the dark and the elec-

Fig. 2 Current potential characteristics: a, Illuminated CdS layer (0.5 cm^2) in molar Na_2S , 0.05 mol dm^{-3} S solution, b, Illuminated CdSe layer (0.5 cm^2) in $1 \text{ M Na}_2\text{S}$, 0.05 mol dm^{-3} S solution. c, 10 cm^2 Pt counterelectrode in molar Na_2S , 0.05 mol dm^{-3} S solution.

trolyte, molar Na_2S , was continuously purged with argon. Fig. 1 shows the anode potential with respect to a saturated calomel electrode (SCE) as a function of charge passed. The initial potential shows that the reaction was self-driving according to the equations

(for example) $\text{Cd} + \text{S}^{2-} \rightarrow \text{CdS} + 2\text{e}^-$ $E \approx -1.06 \text{ V}$ at anode

and $\text{e}^- + \text{H}_2\text{S} \rightarrow \text{HS}^- + \frac{1}{2}\text{H}_2$ $E \approx -0.75 \text{ V}$ at platinum cathode

As the CdS film grew, the anode potential rose corresponding to the field required to assist diffusion of Cd^{2+} or S^{2-} ions through the CdS lattice. The potential did not rise above -0.6 V , suggesting that some current was thereafter being diverted to a competitive reaction, for example

The thickness of the film can be estimated by applying Faraday's law to the integrated current. We conclude that growth becomes very slow after about $0.1 \mu\text{m}$. Anodisation of Cd in molar Na_2S , S at 0.5 mol dm^{-3} solution gave similar results. Fig. 1 also shows the result of anodising Cd in molar NaOH saturated with selenium—a solution known to contain polyselenide and selenide ions. This time we see that the competitive reaction occurred much earlier, so that thicknesses of above $0.01 \mu\text{m}$ were difficult to achieve by this method. Since a thicker layer would be required to efficiently absorb light, alternative methods of preparation were investigated. One method was the immersion of Cd in a boiling solution of KOH at 5 mol dm^{-3} saturated with selenium. After some hours treatment, a black layer was revealed on the Cd surface after removal of selenium in boiling Na_2S solution. We presumed this layer was CdSe.

Figure 2 shows cell current plotted against electrode potential for the cadmium sulphide and selenide films illuminated by direct sunlight in a solution of molar Na_2S , 0.05 mol dm^{-3} S. The potential was measured against an SCE immersed in the solution while the current passed through a platinum counterelectrode. In this way the potential of the photovoltaic electrode was observed undistorted by any overvoltage developed on the platinum. Approximate conversion efficiencies, assuming no overvoltage on the counterelectrode, were 0.4% for CdS and 1.0% for CdSe.

We have shown that films of CdSe may be prepared by an economically attractive process, involving no high temperatures and using a minimum amount of the less abundant element, selenium. The films were shown to have a greater efficiency than similar sulphide films as expected from band-gap considerations. Further work involving alternative preparations

of the films is showing efficiencies significantly greater than that reported here, and stability tests have as yet shown no signs of film degradation.

Iceberg deterioration

A VERY large tabular iceberg was observed as it drifted north-east of the Grand Banks of Newfoundland during May and June 1976. When the iceberg was first sighted on 12 May 1976 it showed only minor signs of deterioration. From 12 May until last sighted on 6 June the iceberg underwent a rapid reduction of the above water surface area with the erosion largely confined to the turbulent layer associated with gravity waves. The erosion progressed along lines parallel to the structure of the iceberg as indicated by the pronounced ridge pair seen in the photographs (Fig. 1), a trellis drainage pattern, and an alternation of light and dark bands over the entire surface of the iceberg.

Photographs were taken of a large number of icebergs during the 1976 flights of the International Ice Patrol, operated by the US Coast Guard. These photographs are to be used for a study of iceberg populations off the Grand Banks of Newfoundland (Fig. 2). Black and white photographs (9-inch format) were taken from altitudes of between 300 and 3500 m.

Among the photographs obtained are a unique series of five taken of the same iceberg over a period of 25 d (Fig. 1). It is highly unusual for an iceberg to be relocated over such an extended period when positive identification is possible. Icebergs normally change their appearance so radically by a combination of calving, melting and rolling that it is impossible to positively identify them after only a few days. In this case the unusually low profile, only 4-5 m of elevation, and tabular shape maintained the iceberg in an extremely stable condition.

From 12 May to 6 June 1976 the iceberg decreased in surface area from approximately $190,000 \text{ m}^2$ to an area of $109,000 \text{ m}^2$. The rate of decrease in surface area was nearly linear (Fig. 3) and resulted from wave erosion, undercutting and minor calving. The surface water temperature was $2-4^\circ\text{C}$. Sub surface temperatures in this area typically decrease to a minimum of less than -1°C at 75-100 m depth.

Wave erosion was concentrated at those points which appear as slight irregularities in the 12 May 1976 photograph. The progressive enlargement of these embayments was the result of the local concentration of wave energy and continued bathing of the ice by the turbulent water. The embayments seemed to extend only several metres below the water's surface and have an orientation parallel to the structural features of the iceberg. The underwater shape of the iceberg is not known but it is suspected to have had a flat bottom as inferred from the long term maintenance of its top parallel to the sea surface.

The iceberg seemed to be of land ice origin. Analysis of a piece of the iceberg, recovered by the USCGC Evergreen, showed it to be fresh water ice. The characteristic air bubble bands of glacier ice were visible and surface melt tests produced a pattern of hexagonal depressions

Fig. 1 The deterioration of an iceberg showing the progressive enlargement of embayments. *a*, Photograph 1708Z, 12 May 1976. 49°19.9'N, 49°33.3'W. Area 190,485 m². *b*, 1804Z, 13 May 1976. 49°28.9'N, 49°26.6'W. Area 189,126 m². *c*, 1404Z, 31 May 1976. 48°09'N, 49°34'W. Area 137,361 m². *d*, 1343Z, 4 June 1976. 47°39.7'N, 49°15.8'W. Area 121,113 m². *e*, 1812Z, 6 June 1976. 47°31'N, 49°07'W. Area 109,067 m². Scale bar, 100 m.

approximately 2 cm across which typify the crystalline melt surface texture of glacier ice. The two linear parallel ridges in the upper third of each picture of Fig. 1 are the most obvious manifestations of the ice structure. In the original photographic prints a pattern of trellis drainage can be seen which indicates structural control. There is also an alternation of light and dark bands which while quite subtle are obvious on close examination of an original photographic print. The banding is not a result of the drainage pattern since it is crossed by drainage channels in numerous locations. The band pairs do not seem to be regularly spaced nor are they perfectly linear or parallel for the width of the iceberg. We feel that such a structure is likely to be the result of flow and that the light and dark bands represent streamlines. The two parallel ridges are possibly the result of shear or flow over an irregularity of the glacial bed.

The iceberg's origin remains unknown. The Ward Hunt ice shelf on northern Ellesmere Island, Petermann Glacier in Hall Basin and Humboldt Glacier in Kane Basin are all capable of producing a thin tabular iceberg. Usually such icebergs fragment and deteriorate before they reach 50°N latitude. The last sighting of a similarly-shaped iceberg on

the Grand Banks by the International Ice Patrol was in 1964 (ref. 1). Twenty large tabular icebergs, some as long as 600 m, were sighted by the Ice Patrol aircraft in late February of 1964 between Hamilton Inlet and Cape Chidley. They appeared as far south as 44°N by early May 1964. These icebergs were thought to have their origin in ice island WH-5 which was observed to block the Kennedy Channel from the Canadian shore to Hans Island in 1963 (ref. 2).

Fig. 2 Drift track of a large tabular iceberg near the Grand Banks of Newfoundland.

Fig. 3 The reduction of the sea level horizontal cross-sectional area as a function of time.

A low tabular berg of this size is quite unusual and fortunately rare. It represents a greater than usual hazard for surface vessels due to its lower probability of detection particularly in a seaway. The iceberg's uniqueness contributed to the attention given it by the International Ice Patrol.

Upwelling by icebergs

A CASE is made for considering the influence of melting icebergs on the oceanographic characteristics of the Weddell Sea. In particular, the equivalent upwelling produced by melting must play a large factor in the supply of nutrients to the surface layers of this ocean. It might be, for example, that the slowly moving icebergs leave behind a trail of nutrient enhanced surface fluid. The need for testing such a hypothesis is clear.

In Antarctica the net annual yield of icebergs from the ice shelves and direct glacier streams is of order 10^{15} kg (ref. 1). The major shelf regions are the Ross, Amery and Ronne-Filchner. The latter supplies icebergs to the Weddell Sea at an annual rate of about 0.12×10^{15} kg; a similar amount is estimated to enter this sea from direct glacier streams and smaller shelves. The average density of the ice is 0.85 g cm^{-3} (ref. 2) and its temperature near the edge of the shelf of origin is of order -10°C (ref. 3).

Gordienko⁴ produced a sampling of the size distributions of icebergs off the coast of East Antarctica near the Amery ice shelf. His data show that one-half of the individual icebergs have standing heights above water of from 28 to 65 m, with frequency uniformly distributed between these limits. Average length of iceberg is about 1 km (ref. 4) although individual bergs have been reported with lengths of 45 and 70 km (ref. 5). Total iceberg accumulation in the Antarctic Oceans has been estimated at 6×10^{15} kg, which implies an average iceberg lifetime of about 6 years (ref. 1).

Studies have been reported on the economic usefulness of transporting Antarctic icebergs to lower latitudes as sources of potable water (refs 1 and 6), but no study has been reported on the role that the icebergs have in modifying the structure of the oceans in which they melt. Surface circulation in the Weddell Sea is part of a large clockwise gyre; hence the region tends to retain icebergs and the potential for modification of its near-surface structure of temperature and salinity by the icebergs is greater than that for other Antarctic locations. The results given here show that the icebergs have a significant role in causing the upwelling of waters from below the pycnocline into the shallow upper layer, and that a significant amount of buoyant potential energy is released into the upper layers of the ocean by the melt process.

The vertical structure of the upper waters of the Weddell Sea are typically as shown in Fig. 1 where the temperature and σ_t data for three stations from the 1973 Glacier cruise⁷ are given. The base of the pycnocline is at about 50 m depth. Below the pycnocline is Atlantic Warm Deep Water. An iceberg of 45 m height above water (the modal value of the Gordienko distribution) would extend some 200 m below the pycnocline and its melt water and heat sink properties would be available for modification of this water. A two-layer approximation to the representative structure shown in Fig. 1, averaged over all of the Glacier data for the Weddell Sea in Jan-Feb 1973 would be as shown in Table 1.

The potential energy released by melting below the pycnocline, and thus available for mixing between the two layers can be estimated. We assume that the dominant melting rate occurs along the sides of the iceberg. The potential energy released below the pycnocline is

$$\text{P.E.} = 0.85 \int_{25,000}^{5,000} \Delta \rho g z dz = 6.4 \times 10^9 \text{ erg per cm}^2 \text{ ice column}$$

where $\Delta \rho$ is the density difference between melt and ambient water and is of the order $25 \times 10^{-3} \text{ g cm}^{-3}$.

If melting along the bottom of the iceberg is the dominant rate, the potential energy released below the pycnocline is slightly greater than calculated above since the iceberg will sink

Fig. 1 Representative temperature and density structure of upper waters of the Weddell Sea⁷. Stations are located as follows: station 8: $63^\circ 26'S$, $26^\circ 45'W$; station 16: $68^\circ 50'S$, $18^\circ 20'W$; station 20: $70^\circ 10'S$, $15^\circ 10'W$. Dashed lines show a two-layer approximation based on an average of all 1973 Glacier stations in the Weddell Sea.

as the bottom melts and hence more ice melts below the pycnocline than in the case of melting along sides only. The opposite holds if melting above the water line is the dominant rate.

It is worth while to compare this energy release within the lower layer with that transferred from wind stress at the surface. The 1.2×10^{14} kg of icebergs produced annually by the Ronne-Filchner shelf alone represent $4.8 \times 10^{13} \text{ cm}^3$ of mode thickness bergs. Total energy release is then $3.1 \times 10^{23} \text{ erg yr}^{-1}$ or about $10^{15} \text{ erg s}^{-1}$. A usual wind stress figure is 1 dyn cm^{-2} . Niiler⁸ has shown that the wind related energy which passes through the mixed layer is then about $1 \text{ erg cm}^{-2} \text{ s}^{-1}$. Thus, the energy input by iceberg melt is roughly equivalent to the average wind stress input over an area of 10^6 km^2 .

Consider an iceberg of density 0.85 g cm^{-3} , area of 1 km^2 and extending 250 m into the water. That portion of the iceberg extending below the pycnocline contains $1.7 \times 10^8 \text{ m}^3$ of melt water. What is the ultimate disposition of this melt water?

We assume first that all ice melt mixes with surrounding lower layer fluid to produce a fluid of density equal to that of surface water, that is, water at 0°C , 34.00‰ and that all mixture water ascends to the surface. Let V_1 be the volume of 34.57‰ water

Table 1 Two-layer approximation to a representative temperature and density structure of the Weddell Sea averaged over all of the Glacier data for Jan.-Feb. 1973

Upper layer Thickness 50 m		Below pycnocline	
At 20 m		At 150 m	
Temperature	-1.8 to 0.6°C	Temperature	0.2°C
Salinity	33.94% { $+0.29\%$ -0.55%	Salinity	34.57%

required by the mixture to attain density equal to that of surface water, and V_2 the resultant volume of the mixture. Then

$$V_2 - V_1 = 1.7 \times 10^8$$

and

$$34.57V_1 = 34.00V_2$$

Solving for V_2 , one obtains 10^{10} m^3 of mixture water of density equal to that of surface water, for each square kilometre of iceberg. The vertical migration time of the mixture will be short relative to the melt time of the iceberg. Hence, if the iceberg melts uniformly within one year, an average vertical volume transport of mixture water into the upper layer would be of the order $3.3 \times 10^8 \text{ cm}^3 \text{ s}^{-1}$.

Vertical velocities found in the Oregon Coastal Upwelling zone are of the order $10^{-2} \text{ cm s}^{-1}$ (ref. 9). Thus the area of coastal upwelling required to produce an annual vertical transport equivalent to that of the 1 km^2 iceberg is 3.3×10^{10} or 3.3 km^2 .

Since the iceberg presumably melts at a uniform rate throughout the year, whereas Oregon upwelling is effective only 3 months each year, the coastal upwelling equivalent area may again be increased by a factor of four, to a value of 13.2 km^2 per each square kilometre of iceberg.

In contrast to coastal upwelling, iceberg upwelling is permanent. In Oregon waters, for example, some fraction of the nutrients which are contained in the upwelled water are returned to the deeper zones unused at the time of subsequent sinking of the upwelled waters at the frontal zone. We estimate a 50% utilisation of nutrients in the Oregon case (Lawrence F. Small, personal communication). Then one must again increase the coastal upwelling equivalent area by a factor of two, to 26.3 km^2 .

For an annual iceberg production in the Weddell Sea region of $1.2 \times 10^{14} \text{ kg}$, or $1.2 \times 10^{11} \text{ m}^3$, the number of square kilometres of mode sized icebergs produced and melted each year is 1,400. In terms of area of upwelling equivalent to that of Oregon coastal upwelling, the Weddell Sea has $1,400 \times 26.3$ or $36,800 \text{ km}^2$ of such area. Stated another way, since the Oregon coastal upwelling region extends some 10 km to sea, the upwelling produced in the Weddell Sea by melting icebergs is equivalent to some 3,700 km of Oregon coastline, a distance approximately equal to the length of coastline of the North American continent from Acapulco, Mexico to Ketchikan, Alaska.

The importance, as shown above, of upwelling by icebergs in Antarctica is striking, and one immediately returns to question the validity of the underlying assumptions. Two of the assumptions are critical: first, that melt water entrains sufficient ambient fluid to acquire a density equal to that of fluid in the surface layer, and second, that all of the mixture reaches the surface layer. A key element in evaluating the validity is to examine the Grashoff number which characterises a free convection regime along a vertical wall at which buoyant energy is generated.

For a vertical, heated wall in air, the Grashoff number is given by¹⁰

$$N_{Gr} = \frac{l^3 \rho^2}{\mu^2} g \beta (T_f - T)$$

where l is the characteristic vertical length (the depth of the iceberg below the pycnocline), ρ is the density, g is gravity, β is the thermal expansion coefficient, T_f is the fluid temperature in the field far from the wall, T is the wall temperature, and μ is the fluid viscosity. In the case of iceberg melt, the Grashoff number is predominantly affected by the density difference between that of melt water, ρ , and that of surrounding saline sea water, ρ_f : hence

$$N_{Gr} = \frac{l^3 \rho^2 g}{\mu^2} \left(\frac{1}{\rho} (\rho_f - \rho) \right)$$

For a density difference ($\rho_f - \rho$) of 0.025 g cm^{-3} , one obtains a Grashoff number of the order of 10^{17} . This is an extremely high value which places the vertical flow along the sides of the melting iceberg clearly within a fully turbulent state. For this reason, it is reasonable to assume the conditions stated above.

An iceberg with a plane bottom coincident with a level surface will not cause free vertical convection since the melt fluid along the bottom is constrained from rising by the iceberg itself. If the bottom is tilted relative to a level surface, melt fluid will experience vertical acceleration although the Grashoff number would be smaller than that which characterises flow along vertical sides. Clearly, some bottom melting must occur, hence the released energy estimation previously stated is conservative.

New type of igneous layering due to fractionation of Archaean ultramafic magma

RESEARCH into the petrogenesis of the Bulong Complex¹, near Kalgoorlie, Western Australia (Fig. 1), has indicated that it is composed largely of layered ultramafic cumulates which exhibit both phase and cryptic layering indicative of low pressure fractionation of Archaean ultramafic magma.

The Bulong Complex covers some 200 km^2 but its greatest stratigraphic thickness is only 1.1 km. Detailed research¹ has indicated that the complex originated as a series of liquid-rich, ultramafic magma pulses which were introduced, largely concordantly, into an extensive, but narrow, stratigraphic zone of the originally flat-lying, host formation.

Fig. 1 Geological setting of the Bulong Complex (hatched areas).

Smaller ultramafic pulses either froze to form homogeneous olivine-rich, 'quench-texture' sills or underwent flowage differentiation, before freezing, to form crudely zoned ultramafic sills with olivine-rich cores. Larger ultramafic pulses, on the other hand, differentiated *in situ*, largely by gravitational processes, to produce layered olivine-rich sills which are capped in part by layered pyroxene and pyroxene-plagioclase bearing horizons. During fractionation, small pulses of derivative ultramafic to acid magma were probably tapped off at various stages and intruded about the top of the complex to form the numerous small sills and dykes which are now observed in that position. When igneous activity had virtually ceased the complex and its host rocks were regionally folded (three periods of variably tight to open folding are evident and the complex is even locally overturned) and metamorphosed to middle greenschist grade^{1,3}.

Layered, olivine-rich sills constitute most of the complex and in most localities 3 to 5 sills, stacked one on top of the other and separated in part by thin sheets of country rock, are evident. The sills mainly range in thickness from 350 to 400 m and although all have been deformed, serpentinised and regionally metamorphosed, primary textural features are well preserved and primary mineral relics are not uncommon. The least altered sills contain thin (1–3 m thick) remnant basal 'chilled border' zones composed of olivine-rich, porphyritic spinifex rock⁴ (the presumed quenched starting liquid)¹. About 95%, or more, of the overlying layered rocks are olivine cumulates, which contain accessory amounts of cumulus chromite, in which the proportion of orthocumulus material increases gradually from about 5%, or less, in lowermost parts to 30%, or more, in uppermost parts. The orthocumulus minerals in decreasing order of abundance, are clinopyroxene, orthopyroxene and plagioclase, although hornblende and biotite also occur as orthocumulus phases near the tops of some sills. The thick, layered olivine-(chromite) cumulate zones are capped in part by thin orthopyroxene cumulate layers which are in turn capped successively by thin orthopyroxene-clinopyroxene and plagioclase-clinopyroxene-orthopyroxene cumulate layers. In at least one of the sills a thin chromitite (chromite cumulate) layer is located directly beneath the orthopyroxene cumulate layer. All sills exhibit normal cryptic layering delineated by slight, but consistent iron enrichment in relict olivine (Fo 93 to Fo 86), chromite ($\Sigma\text{FeO}=18$ to 36 wt%; $a_0=8.26$ to 8.31 Å) and clinopyroxene ($\text{Ca}_{15}\text{Mg}_{51}\text{Fe}_4$ to $\text{Ca}_{12}\text{Mg}_{49}\text{Fe}_9$) with increasing stratigraphic height. Clinopyroxene occurs mainly as an intercumulus phase but topmost clinopyroxenes are cumulus and co-exist both with cumulus orthopyroxene (En15) and cumulus plagioclase (An 80 to An 85). Within the main layered olivine-(chromite) cumulate zones there is a marked upward increase in whole rock Ti (1,000–3,000 p.p.m.) and P (50–200+ p.p.m.) content and a marked decrease in Ni (3,500–1,000 p.p.m.) content. This is largely a reflection of the gradual upward increase in the proportion of orthocumulus material¹.

The field evidence^{1,2} suggests that at the time of emplacement of the layered sills the confining pressure due to overlying rocks was only about 1 to 2 kbar and this is supported by (1) high CaO content (0.3–0.5 wt%) in relict olivine^{5,6}, (2) moderate to high $\text{Al}^{\text{IV}}/\text{Al}^{\text{VI}}$ (>2) ratios⁷ and TiO_2 contents (0.2–0.6%) (ref. 8) in relict clinopyroxene, (3) abundant evidence for reaction between settled olivine and trapped liquid⁹ before onset of intercumulus pyroxene crystallisation and (4) by a general lack of evidence for subsolidus reaction between cumulus olivine and intercumulus plagioclase¹⁰. Furthermore, simplified low-pressure (1–2 kbar) phase relations for the system olivine-clinopyroxene-plagioclase-quartz¹¹ accurately predict the observed crystallisation sequence obtained using the mean composition of the basal, chilled contact rocks¹. The one

known chromite horizon is thought to have simply formed as a 'lag deposit', partly because of the peritectic relation between orthopyroxene and chromite¹² (that is, orthopyroxene precipitation suppresses chromite precipitation) and because of the relative settling rates of olivine (coarse-grained) and chromite (very fine-grained)¹⁴.

Liquidus phase relations for natural ultramafic rock of similar composition to that of the chilled contact rock (Table 1)¹³ clearly indicate that the ultramafic magma pulses which gave rise to the Bulong Complex were low in water content (1–2 wt%) and were also emplaced at temperatures slightly in excess of 1,650 °C. Finally, the TiO_2 content of the mean chilled contact rock (Table 1) suggests that it was derived by approximately 60% partial melting of an Archaean upper mantle source¹⁵.

Table 1 Chemical analyses of ultramafic quench rocks (recalculated anhydrous)

	Ultramafic quench rock from South African Archaean flow ¹³	Mean basal chilled contact rock in Bulong Complex (5 analyses)
	a	b
SiO_2	46.5	43.4
TiO_2	0.2	~0.25
Al_2O_3	3.6	4.5
ΣFeO	10.3	7.0
MgO	33.0	39.0
CaO	5.0	3.1
Na_2O	0.5	0.4
K_2O	0.2	0.2
Cr_2O_3	0.4	0.4
NiO	0.3	0.3
$\text{CaO}/\text{Al}_2\text{O}_3$	1.4	0.7

Discovery of the phase and cryptic layering reported here has not only extended our knowledge of the spectrum of Archaean ultramafic rock types, which up until now has included various types of zoned and unzoned non-layered sills and flows (refs 4, 15–17), but has also broadened our knowledge of the total spectrum of layered igneous rocks¹⁸. A detailed account of phase and cryptic layering in the Bulong Complex is in preparation.

Effects on biological evolution of changes in ocean chemistry

PERHAPS the most perplexing problem of biological evolution involves explanation of why diversification of life began only after 85% of the lifetime of the Earth while simple life seems to have been present for virtually all of geological time. Recent observations¹⁻² on the presence of complex organic species in meteoritic debris and in the interstellar medium show that some of the basic biological building blocks may have been available from the earliest times. Chamberlain and Marland³ have commented on the biological consequences of the Hargraves⁴ model of ocean-crust evolution while others⁵⁻⁶ have reassessed evidence on atmospheric evolution and indicated that changes in oxygen partial pressure may not have been critical to the diversification of life. In this note I suggest that important changes in ocean chemistry must have occurred if our current models of crustal evolution and igneous events have any validity. The evolution of complex life forms requires a high degree of environmental stability and constancy of chemical environment. It is suggested that this condition is closely linked to the spacing of major volcanic centres, and that the modern long wavelength pattern of ocean ridges and subduction zones was necessary to achieve this stability. The distribution of ophiolites or ocean-floor structures of modern type⁷ indicates that the present pattern may have been initiated about one billion years ago. Furthermore, large scale continental emergence⁴ may have been necessary to provide oceans with stable chemistry.

There is much evidence to support the Hargraves⁴ model of early globe-encircling oceans and slow continental emergence. The ocean mass may have been greater⁸. Further evidence shows that with an early hotter earth, volcanic activity was more intense and that centres of volcanic activity were closely spaced with a wavelength pattern of hundreds not thousands of kilometres. We also know that the cooling of submarine igneous bodies involves convective flow of seawater and that the chemistry of the cold inflow and hotter discharge waters is quite different. Thus, early oceans would tend to reflect volcanogenic discharge more than continental runoff. As such, chemistry would be erratic and frequently concentrations of typical easily transported metals like Cu, Hg, Pb, Zn, Mn, Fe, As, could be large as in the modern Red Sea deeps. (The Red Sea illustrates⁹ the toxic effects of such discharge.)

For the present earth, continental runoff amounts to about 3×10^{10} g yr⁻¹ while the ocean mass is 1.4×10^{24} g. Submarine volcanic activity associated with the ocean-floor spreading process currently adds some 3×10^{16} g of basalt liquids to the ocean annually. This liquid at 1,200 °C cools by convective flow of ocean water. Sites of discharge will cause local changes in chemistry as seen in the Red Sea and many other places^{10,11}. The energy input at modern ocean ridges (4×10^{18} J yr⁻¹) could heat 10^{17} g of sea water to 100 °C. Thus, at present, hydrothermally modified ocean water might approach 1% of the volume of continental runoff. If this water contains any chemical species at much higher concentrations than in river water, it may influence the balance of ocean waters.

Elements that are present at much higher levels than in normal ground waters (100 times) include a host of those which can be toxic to complex life forms (As, Hg, Cu, Zn, Mn, Fe, Pb). Furthermore, if there was little land above sea level in the Archaean, the input of metal absorbing clay mineral would be reduced, and this detoxification process would be less effective¹².

At present, while basaltic mantle-derived volcanic processes are concentrated in the submarine environment, subduction andesite-granite igneous activity is concentrated

on the continents and if convective cooling occurs, it involves less saline waters which in general transport less metal. But in the Archaean, nearly all igneous activity was submarine. The huge granite bodies of the Archaean could generate sustained submarine discharge on a scale not seen today. Imagine the consequences of emplacing the Sierra Nevada Batholith in a submarine environment.

Thus, the Archaean ocean floor may have been populated by closely spaced volcanic centres with an igneous intensity an order of magnitude more than known today¹³. From such centres there would have been an intense discharge of toxic elements and hydrogen into deep basins. In such an environment, one would have expected only the most simple and versatile life forms to survive.

Runcorn¹⁴ has discussed the possibility of quantised changes in mantle convection associated with cooling. If cells have become larger with time, then the current convection pattern may have been necessary for the recent biological diversifications. Fluctuating environmental pollution caused by closely spaced centres of intense submarine volcanism may have inhibited complex biological evolution for most of earth history.

Interaction between effects of vesicular-arbuscular mycorrhiza and fertiliser phosphorus on yields of potatoes in the field

MANY experiments in controlled environments have shown that vesicular-arbuscular (VA) mycorrhizas may benefit the phosphorus uptake and growth of plants¹⁻⁴, depending on the nature and level of indigenous inoculum, the phosphorus status of the soil and other factors⁵⁻⁷. But there have been few reports of attempts to obtain larger crops, or reduce phosphorus fertiliser requirement, by manipulation of VA mycorrhizal infection in field crops⁸⁻¹². We report here the effect on potatoes of an artificial increase in the level of VA infection. Potatoes are known to have VA mycorrhizas¹³⁻¹⁶, and their sparse rooting systems¹⁷ and heavy phosphorus demand suggest that they should respond to infection. This is the first report of a successful field inoculation experiment on a major field crop in temperate zone conditions.

The method of inoculation depended on observations, made in a separate experiment, on the changes of spore number and extent of infection caused by different cropping sequences. Cropping with cereals tended to induce high spore density, with heavy infection of subsequent crops, whereas if the area was left fallow there was a rapid decline in spore density and subsequent level of infection (Table 1).

The potato experiment was sited on an area left fallow for 2 yr, so that the spore density was only about one per ml. The inoculum consisted of topsoil from nearby plots,

Table 1 Effect of crop sequence on VA mycorrhizas in barley, together with spore density in soil

Growing season		Infection in August (% of root length)	Spore density (no. per ml of soil, fraction retained on 45-µm sieve)	
			Spring	Autumn
1975	Continuous barley (4 yr)	39	29	21
	Barley after 1 yr fallow	21	18	10
1976	Continuous barley (5 yr)	19	17	17
	Barley after 2 yr fallow	5	4	Not measured

on the same soil series, on which barley had been grown for 3 yr, and which contained 13 spores per ml. The most frequent spore type was identified as *Glomus macrocarpus*¹⁸. The experimental plots were 3.05 m × 3 m, and received ammonium nitrate (437 kg ha⁻¹) and potassium chloride (502 kg ha⁻¹) fertiliser broadcast before planting of Pentland Javelin seed potatoes. They were treated with triple superphosphate (0 or 481 kg ha⁻¹), combined factorially with presence or absence of soil inoculum. The latter was applied down the furrows at about 3 kg m⁻². It contained available (Olsen) phosphorus at 15 µg g⁻¹, compared with 7 µg g⁻¹ in the plot soil; the amount of added available phosphorus was therefore extremely small compared with any useful fertiliser dressing. Uninoculated plots received the same amount of topsoil from the fallowed area. There were four replicates. During the period of growth, soil core samples were taken, the roots in them were washed out and percentage infection was determined¹⁹.

Infection spread most between the first two root samplings (Table 2). Infection with soil inoculum was much greater than the very low control level but, as expected, phosphorus fertiliser suppressed it considerably. No treatment had a significant effect on phosphorus in leaflets sampled on 12 July (Table 2), possibly because leaf senescence was becoming general.

At harvest, fertiliser phosphorus increased yield, but least so in the presence of cereal soil inoculum. Interaction between inoculum and fertiliser phosphorus is indicated by the large increase in yield caused by inoculum, but only in the absence of phosphorus fertiliser.

An important purpose of our trial was to test the effectiveness of a relatively small amount of soil as inoculum for VA mycorrhizal infection. Rich and Bird¹⁰ reported successful use of imported soil containing twice as many spores as the soil at the experimental site, whereas our soil inoculum had more than 10 times as many spores as the field soil, but was used in smaller quantities. The micro-

biological population of the inoculum soil and the plot soil must have differed in many respects, including their content of pathogenic organisms, because of their different cropping history. Other organisms in the inoculum soil may have infected or altered the crop, but the increase in mycorrhizal infection, and the interaction with phosphorus fertiliser, leaves little doubt that it was principally VA organisms which affected the yield.

Our experiments illustrate two important points. First, the effects of cropping rotation on the VA infection of subsequent crops must always be considered²⁰. Second, the phosphorus status, fertiliser response and economics of the use of fertiliser for mycorrhiza-forming field crops may depend greatly on the degree of infection, and work on these may be incomplete unless infection is measured. The frequent difficulty of correlating phosphorus requirement of a crop and soil analytical results may also be due to differences in VA infection.

Chemical activation of host defence mechanisms as a basis for crop protection

THE possibility that a chemical for plant disease control might function by activating the natural resistance mechanisms of the host has been suggested previously¹, but there are few well-documented examples. We report here that 2,2-dichloro-3,3-dimethyl cyclopropane carboxylic acid (WL 28325) may exert its systemic fungicidal activity against the rice blast disease (caused by the fungus *Piricularia oryzae*) in this way.

It is unlikely that the WL 28325-induced resistance of rice to blast can be attributed to either the direct action of the fungicide on the parasite or the production of fungitoxic derivatives within the plant². There is, however, evidence to suggest that WL 28325 acts by sensitising the host such that subsequent inoculation with *P. oryzae* results in a resistant reaction. Both the natural and the WL 28325-induced resistance of rice involve a hypersensitive type of browning reaction (as is commonly found in incompatible plant-fungus interactions) presumed to be a localised accumulation of melanoid pigments in the plant cells resulting from the peroxidase-mediated oxidation of phenols. This response is accentuated and accelerated by previous treatment of the plants through the roots with WL 28325 (ref. 3).

Microscopic observations of the infection process on

Fig. 1 Effect of WL 28325 treatment and *P. oryzae* infection on the inhibitory activity of drop diffusates against germ tube growth. ●, WL 28325-treated and infected; ○, untreated and infected. Each point is the mean of three replicate samples.

leaves showed that germination and appressorium formation by spores of *P. oryzae* were similar on WL 28325-treated and untreated plants. The internal development of the disease was examined in toluidine blue stained transverse sections of wounds on leaves of treated and untreated plants. In untreated leaves examined 48 h after inoculation, fungal hyphae were observed spreading throughout the vascular bundles of the inoculated wound. In the following 40 h the hyphae increased in number and spread into the tissue surrounding the wounded area. Hyphae were rarely observed in inoculated wounds of treated leaves, however, even 96 h after inoculation. This suggests that WL 28325-induced resistance of rice to *P. oryzae* might involve a more direct suppression of fungal growth rather than a physical restriction of the fungus to the inoculated area by the brown melanoid pigments as suggested previously³.

This possibility was substantiated when infection droplets were removed at intervals from the wounds on treated and untreated leaves and tested against germ tube growth of *P. oryzae*. When compared with spores germinated in distilled water, inhibition of germ tube growth was evident in diffusates collected from treated, infected leaves (Fig. 1). Diffusates collected from untreated, infected leaves were considerably less inhibitory while those collected from uninfected leaves, either treated or untreated, showed no antifungal activity. Repeated experiments confirmed that this antifungal activity induced by infection with *P. oryzae*, was enhanced by treatment of the plants with WL 28325 before inoculation.

Similar results were obtained using ethanolic extracts of infected leaves rather than drop diffusates. The extracts were subjected to thin-layer chromatography (silica gel; solvent system, chloroform-ethanol (95:5v/v) followed by a direct bioassay for antifungal compounds using *Cladosporium cucumerinum*⁴. This revealed two major antifungal zones in chromatograms of extracts of infected leaves. Chromatograms of extracts of uninfected leaves showed no such inhibitory areas. Similar antifungal activity could be induced by ultraviolet irradiation of either leaves or dark-grown coleoptiles of rice. In these conditions antifungal activity was not influenced by treatment of the plants with WL 28325. Elution of the antifungal zones from the chromatograms showed that the areas of the chromatograms which inhibited *C. cucumerinum* also inhibited *P. oryzae*.

Fungal infection thus induces the production of antifungal compounds which may be defined as phytoalexins—antimicrobial compounds formed by plants in response to

injury, physiological stimuli or the presence of infectious agents. As the phytoalexins are induced in untreated rice plants following ultraviolet irradiation they are clearly of host and not fungal origin and they are not antifungal derivatives of WL 28325.

The two major phytoalexins were isolated in small quantities as chromatographically homogeneous amorphous solids from ultraviolet-irradiated dark-grown rice coleoptiles by column chromatography on Sephadex LH-20 and preparative thin-layer chromatography on silica gel. Electron impact (EI) and field desorption (FD) mass spectrometry of the less polar compound showed a molecular ion at m/e 314. The more polar compound showed no clearly recognisable molecular ion by EI mass spectrometry but by FD mass spectrometry a presumed molecular ion at m/e 330 together with a strong $M+1$ ion was obtained. Detailed analysis of the 270-MHz proton magnetic resonance (PMR) spectra indicated their probable identity with momilactones A (I) and B (II). These two 9- β -pimaradiene diterpenes have been isolated as plant growth inhibitors from rice husks^{5,6}. Comparisons by combined gas-liquid chromatography (GLC)-mass and PMR spectroscopy of the phytoalexins isolated from rice with authentic samples subsequently confirmed their identity with the momilactones A and B. Optical rotation measurements showed that they also have identical stereochemistry. Yields of the momilactones A and B isolated from ultraviolet-irradiated coleoptiles were 3.8 and 0.9 mg per kg fresh weight respectively while estimated recoveries were 70 and 50% of the momilactone content of crude extracts. Combined GLC-mass spectroscopy confirmed the presence of the momilactones A and B in extracts of infected leaves and these two compounds account for all the antifungal activity of the crude extracts. Concentrations giving 50% inhibition of germ tube growth of *P. oryzae* for the momilactones A and B were 5 and 1 $\mu\text{g ml}^{-1}$ respectively.

We believe that this report is the first in which phytoalexins have been characterised from a member of the Gramineae, although there have been previous indications that phytoalexins may be produced by rice⁷ and

(I) Momilactone A

(II) Momilactone B

barley⁸. The diterpene nature of the momilactones is a significant departure from all previously described phytoalexins, these being mostly phenols or sesquiterpenes⁹. A diterpene hydrocarbon from *Ricinus communis*, casbene, may have some of the properties of a phytoalexin although its production in response to infection was only reported for cell-free extracts¹⁰.

While certain fungicides are themselves capable of eliciting phytoalexin production¹¹, the activity of WL 28325 is unique in that the compound itself does not stimulate phytoalexin production but rather it increases the capacity of rice to synthesise phytoalexins in response to infection—this may be the basis for its disease-protectant properties. It is hoped that future studies on the effects of WL 28325 on the host-parasite relationship in the rice blast disease will not only provide further insight into the processes of natural resistance of rice to disease but will also indicate ways in which host defence mechanisms can be manipulated to control plant disease.

We thank Dr T. Kato for samples of momilactones A and B.

Stimulation of egg-laying by nerve extracts in slugs

LITTLE is known about the mechanism of egg-laying in mollusca, although their reproduction is under endocrine control. In the freshwater snail *Lymnaea stagnalis*, cauterisation of the neurosecretory caudodorsal cells of the cerebral ganglia causes cessation of oviposition. Subsequent injection of a homogenate of cerebral commissures induces oviposition in all snails with caudodorsal cells. This suggests that the caudodorsal cells produce a hormone, which

stimulates oviposition¹. Kupfermann² induced ovulation and oviposition in *Aplysia californica* by injection of a homogenate of neurosecretory cells, the so-called bag cells, from the abdominal ganglion of this species. Although the morphology of the reproductive system has been studied in various terrestrial slugs^{3–7}, there are conflicting reports about the control of reproduction. I report here that homogenates of the central ganglia and tentacles, which are the sites of neurosecretory cells^{8,9}, stimulate egg-laying in the slugs, *Deroceras reticulatus* (= *Agriolimax reticulatus*) and *Limax flavus*.

Egg-laying in *D. reticulatus* occurs throughout the year, reaching peaks in April and October while in *L. flavus* the breeding season is May to November. I used slugs during their breeding season. Brains and tentacles were extirpated and homogenised in physiological saline. Then they were injected into the body cavity at a dose of four or five homogenised organs per slug. The rate of fertilisation, as represented by the hatching rate, of oviposited eggs was also examined. After 7 d oviposited eggs were counted.

The results are shown in Table 1. Brain hormone (homogenate of central ganglia) stimulated egg-laying and tentacular hormone (homogenate of tentacles) inhibited egg-laying in both species. To investigate the nature of the active principles in the homogenates, the effects of boiling and dialysis of each sample were studied. Table 1 shows that the results were similar to those for crude extracts—the treated homogenates of ganglia and tentacles still stimulated or inhibited egg-laying. The rate of fertilisation in the group given tentacular hormone was lower than that in the group given brain hormone or in the control groups. Table 2 shows the results of similar experiments on slugs with tentacles extirpated. Removal of tentacles induced a large increase in the number of eggs laid and an increase in the rate of fertilisation in both species. Results of hormone treatment were similar to those observed with intact slugs of both species. Accelerated oviposition and a high rate of fertilisation induced by removal of tentacles was inhibited by injection of tentacular hormone. The injection of brain hormone into slugs without tentacles induced still greater egg-laying and fertilisation in both species. Both hormones remained active in spite of boiling or dialysis. The minimum time between injection and the onset of egg-laying was 6 h. But the effects of the hormones continued for about 7 d. Egg-laying usually commenced 12 h after treatment. In *Lymnaea stagnalis*¹, the mean response latency was 131 min, *Aplysia californica*², it was 72 min but there was a seasonal fluctuation in amount of active principle and/or the ability to respond¹⁴. In *Lymnaea stagnalis*, injection of cerebral commissures into intact snails induced oviposition in most but not all recipients. In my experiments, some individual recipient slugs did not respond to the injection of brain extract.

These results suggest that brain hormone stimulates egg-laying directly, while tentacular hormone inhibits the brain

Table 1 Effects of the injection of brain and tentacular homogenates on oviposition in the slug, *Deroceras reticulatus* (D) and *Limax flavus* (L)

hormone. The role of these hormones in fertilisation remains unclear.

Tentacles have been shown to be neuroendocrine organ⁸⁻¹². In the tentacle, the tentacular ganglion is located close to the eye. It is connected with the procerebrum by the tentacular nerve. It seems likely that the tentacular hormone inhibits the activity of the neurosecretory cells of the central ganglia and as a result, egg-laying is inhibited. This resembles the hypothalamo-hypophysis-gonadal system in vertebrates. As the eye is located near the neurosecretory cells of the optic tentacle, environmental stimuli such as light and day-length, may influence the release of tentacular hormone.

I thank Professor J. Ishida, Toho University, and Dr N. W. Runham, University College of North Wales, for guidance and encouragement, Dr A. Kondo for discussions, and Mr H. Hayashi for technical assistance.

Differential pigmentation in the sexual phase of *Coelomomyces*

THE fungal mosquito parasite, *Coelomomyces dodgei* (Chytridiomycetes: Blastocladales), produces gametophytes and gametangia of two different colours, light amber and bright orange, in the intermediate copepod host, *Cyclops vernalis*. Each gametangium produces gametes of a corresponding colour. Experimental evidence is presented here which indicates that these differentially pigmented gametes are of opposite mating types, the light amber being female and the bright orange being male, and that zygotes capable of infecting mosquitoes, are produced by their fusion. This differential pigmentation provides a valuable marker for identifying gametes of opposite mating type for experimental purposes, and additionally provides further evidence for a phylogenetic relationship between *Coelomomyces* and certain other genera of the order Blastocladales.

Since the 1930s, fungi of the genus *Coelomomyces* have

been considered potential biological control agents for mosquitoes because of their well documented ability to produce epizootics in larval populations¹⁻³. This potential has not been realised or even accurately evaluated because of the difficulties of establishing laboratory cultures for detailed investigations. The primary reason for these difficulties became apparent during the past few years with the discovery that *C. psorophorae*^{4,5} and *C. punctatus*^{6,7}, parasites respectively of the mosquitoes *Culiseta inornata* and *Anopheles quadrimaculatus*, have alternate stages which develop in an intermediate host, the copepod, *Cyclops vernalis*. This finding led to the development of routine reproducible methods for the establishment of *in vivo* laboratory cultures of *C. psorophorae* and *C. punctatus* and more recently has resulted in the establishment of an *in vivo* culture of *C. dodgei*⁸ using *A. quadrimaculatus* and *Cy. vernalis* as alternating hosts.

Two of the above studies^{6,8} have also provided substantial evidence that these three species of *Coelomomyces* have an Euallomycetes type of life cycle with sporophyte and gametophyte generations alternating between the mosquito and copepod host, respectively. In essence, the evidence suggests the following general life cycle, although many details remain to be resolved, including precisely when meiosis occurs. The sporophyte in the mosquito larva produces meiosporangia which release meiospores after death of the host. The meiospores, in turn, infect copepods and develop into gametophytic thalli which subsequently become gametangia and produce gametes. Gametes fuse forming zygotes which infect mosquitoes and produce a sporophyte, thereby completing the life cycle. This cycle was first elucidated by Whisler *et al.*⁹ working with *C. psorophorae* and later by Federici and Chapman⁸ studying *C. dodgei*. The latter authors also observed gametophytes and gametes of two different colour types, light amber and bright orange, which apparently do not occur in *C. psorophorae*, and suggested that this differential pigmentation corresponded with opposite mating types. The present report provides experimental evidence for this hypothesis.

Copepods of *Cy. vernalis* were infected with *C. dodgei* using methods similar to those of Federici and Chapman⁸. Several hundred copepods were combined with about 5,000 dehiscing meiosporangia in 1 l of deionised water to which approximately 50 mg each of brewer's yeast and egg yolk had been added 48 h previously. Ten cultures were prepared in this manner and pooled 10 d later. The copepods were removed from the medium with a net every day from the 13th to the 18th day after exposure to the dehiscing meiosporangia. Patently infected adult copepods, which varied in colour from light amber to bright orange, were separated from the other copepods and the latter were returned to the medium. Infected copepods were examined individually with a phase microscope to confirm the colour

of the gametangium(a) in the haemocoel. The intensity of the colour, that is, the amount of pigmentation, frequently varied, especially in orange plants, from one copepod to another, but generally the infected copepods could be separated into three different types; those containing (1) only bright orange gametangia; (2) only light amber gametangia; and (3) both types. After separation into types, each copepod was placed in a 35×10 mm Petri dish in 2 ml filter-sterilised filtrate from the original copepod rearing medium. At least 20 copepods of each colour type were so prepared for each experiment. In most cases, the gametangia released the gametes, which were equal in size in both colour types, within 2 h. Shortly after gamete release, the copepod died and ruptured releasing gametes into the medium. The media containing gametes were then pooled in various combinations of type and amount and tested for mosquito infectivity. Unpooled media were also tested for infectivity. This was done by combining the media containing gametes with 20 recently hatched first-instar larvae of *A. quadrimaculatus* in a 60-mm Petri dish for 24 h. The larvae were then transferred to 1 l of rearing medium and examined periodically for infection. Additionally, drops of the pooled and unpooled media were examined periodically with a phase microscope for the presence of biflagellate planonts.

The results are shown in Table 1. No mosquito infection resulted in any test where larvae were exposed to gametes of a single colour type regardless of the number of gametes used. Some infection resulted in all tests where larvae were exposed to mixtures of light amber and bright orange gametes even in cases where both colour types were from the same copepod. Interestingly, the highest infection rates per copepod were obtained in tests where gametes from copepods containing both colour types were pooled, indicating greater numbers of zygotes may be formed if gametes of opposite mating type are produced in the same copepod.

Microscopic examinations were less definitive. In pools of gametes of a single colour type, no fusion was observed on pooling although occasionally bi- and multiflagellate planonts were observed. Although biflagellate zygotes were common in the mixtures of different coloured gametes, the actual process of fusion was observed only infrequently.

These results provide strong evidence for an *Euellomyces* type of life cycle for *C. dodgei* with the differentially pigmented sexual structures, light amber and bright orange,

being of opposite mating type. A similar type of sexual pigmentation is well known in several other *Blastocladiella* with an *Euellomyces* type of life cycle. Where it occurs in the genus *Allomyces*^{9,10}, both female (unpigmented) and male (orange) gametangia occur on the same gametophytic plant, and the resultant female gametes are larger than the males. The case of *Blastocladiella variabilis*, however, more closely resembles the situation in *C. dodgei*. In *B. variabilis* Harder and Sörgel^{11,12} found that unpigmented and orange gametangia developed on separate plants and furthermore, that the resultant gametes, which were of opposite mating type, were equal in size.

The above reports provide a precedent for designating the light amber reproductive structures of *C. dodgei* as female and the bright orange as male. In summary then, *C. dodgei* seems to have an *Euellomyces* type of life cycle with sporophyte and gametophyte generations alternating between a definitive larval mosquito host and an intermediate copepod host, respectively. The meiosporangia which develop on the sporophyte release meiospores after mosquito death. The meiospores infect a copepod and each produces a separate gametophytic thallus which at maturity is converted to one or several gametangia, but releases only a single type of gamete. Female gametangia are light amber and release unpigmented gametes. Male gametangia are bright orange and release orange gametes. One or both sexes can develop in a single copepod depending on whether the infecting meiospore(s) form male or female thalli. Uniflagellate male and female gametes fuse in appropriate conditions forming a biflagellate zygote which completes the sexual cycle by infecting a mosquito larva and producing another sporophyte.

Differentially pigmented mycelia have also been observed in *Cy. vernalis* experimentally infected with *C. punctatus* and it is likely, therefore, that this species has a life cycle similar to that of *C. dodgei*.

The occurrence of differential sexual pigmentation in *Coelomomyces* should enhance efforts to evaluate the mosquito control potential of this fungal group. The orange pigmentation or lack of it can serve as a sexual marker for genetic studies directed towards selecting highly mosquito-infective strains and for investigations on the biosystematics of species of *Coelomomyces* in which this pigmentation occurs.

Genetic variation in multigene families

THE possibility that some important quantitative characters of higher organisms may be subject to multigene families such as that of immunoglobulin variable parts¹, poses the problem of reformulation on some of the population genetics theory. The two remarkable characteristics of multigene families as shown by Hood and others^{1–3}—the contraction and expansion of the gene number in a family and the coincidental evolution—should now

be seriously taken into account in the theoretical investigation of the evolution of higher organisms. In addition, the unit of natural selection is the family itself rather than individual mutant genes. The model of unequal crossing-over provides one of the most satisfactory explanations for the coincidental evolution¹⁻⁴. In this model, the gene lineage gradually expands or contracts within a family mainly by intrachromosomal unequal crossovers. I have shown⁵ that the dynamics of a gene lineage within a chromosome under this model and some other models is analogous to that of a mutant gene in finite populations using the diffusion model of Kimura⁶. Here I present the equilibrium properties of genetic variation of multigene families under simplifying assumptions and show that natural selection may be quite effective in keeping a large amount of variation in the family such as that of variable parts of immunoglobulins.

Let us measure genetic variation of a gene family within a chromosome by the clonality⁴ (C) defined as the sum of squares of gene lineage frequencies within a family,

$$C = \sum_i x_i^2 \quad (1)$$

where x_i is the frequency of the i th gene lineage in the chromosome. Note that the clonality is equivalent to homozygosity in the analogous population genetics model. I also use my previous model⁵ of unequal crossing-over, in which duplication and deletion of one unit by unequal crossing-over occur alternately so that the total number of units, n , in a chromosome is kept constant. Two successive crossovers (duplication and deletion) are called one cycle of the process.

Now the mean change of C by one cycle of crossing over has been shown to be⁴

$$E\{\Delta C\} = 2(1-C)/n^2 \quad (2)$$

where E stands for taking the expectation. In other words, C increases by an amount of $2(1-C)/n^2$ through one cycle of crossover. On the other hand, it decreases by mutation and there is therefore a stable equilibrium between mutation and unequal crossing-over. Let us assume that all mutations are unique and not pre-existing and let ν be the mutation rate per gene unit per generation. Let us further assume that k is the effective number of cycles of unequal crossing-over per chromosome per generation. The changes in clonality per generation by mutation (ΔC_ν) and by crossover (ΔC_k) are then expressed as

$$\Delta C_\nu = -2\nu C \quad (3)$$

$$\Delta C_k = 2k(1-C)/n^2 \quad (4)$$

Note again the analogy of this formulation with that of genetic variability in finite populations by Kimura and Crow⁷. The equilibrium value of C becomes

$$\hat{C} = k/(k+n^2\nu) \quad (5)$$

If k is proportional to n

$$\hat{C} = a/(a+n\nu) \quad (6)$$

where $a = k/n$. So far I have considered a single chromosomal family. Actually, however there are many chromosomal families in the population and ordinary crossing over occurs between the chromosomes. This would decrease the above $\hat{C}$ value. It would be expected that if the population is very large and if the inter-chromosomal exchange is frequent, the average clonality would be greatly reduced. Here if one assumes that the rate of intra-chromosomal crossover is much larger than that of inter-chromosomal crossover as has been assumed by Smith⁸, the present formulation may still apply approximately. The more general treatment is in progress. I shall show later some results of the simulation studies.

Let us now incorporate natural selection between chromo-

somes into the model. Let s be the selective disadvantage at $C = 1$ such that the fitness of a family with clonality C (W) is equal to

$$W = 1 - sC \quad (7)$$

For simplicity, the additive effect of clonality is assumed. Then the mean fitness of the population is

$$\bar{W} = 1 - s\bar{C} \quad (8)$$

and the change in fitness is proportional to the change in C , $\Delta\bar{W} = -s\Delta\bar{C}$. The fundamental theorem of natural selection by Fisher⁹ states that the rate of change of mean fitness of the population is equal to the genetic variance of fitness in the population at that time. In our case, the change of mean fitness per generation may be expressed as

$$\Delta\bar{W} = s^2 V_c / \bar{W} \quad (9)$$

where V_c is the variance of clonality among the chromosomes in a population, hence the change in mean clonality per generation due to selection becomes,

$$\Delta\bar{C}_s = -sV_c / \bar{W} \quad (10)$$

In other words, the mean clonality decreases by an amount $sV_c / \bar{W}$ each generation by this type of selection.

This variance in clonality among the chromosomes (V_c) is the crucial factor which determines the effectiveness of natural selection and represents genetic variability in the sense of population genetics. At the moment, however it seems to be difficult to evaluate V_c . In the population genetics analogy, each chromosome corresponds to subpopulations of lineages, and inter-chromosomal crossing over to migration of mutant genes. Under the simplifying assumptions that the inter-chromosomal crossover is negligibly rare compared to the intra-chromosomal crossing over and that the population size is large without selection, V_c is expected to be roughly equal to Stewart's formula¹⁰ for the variance of heterozygosity in population genetics

$$V_c \approx \frac{2\theta}{(1+\theta)^2(2+\theta)(3+\theta)} \quad (11)$$

in which $\theta = n^2\nu/k$. Such an assumption may not usually be met although my preliminary simulation studies indicate that V_c is not much smaller in magnitude than the above formula suggests relative to the mean clonality even when the assumptions are not met. Thus, by comparing the formulas (3) and (10), it can be seen that natural selection may be more effective than mutation in reducing the average clonality or in increasing genetic variation in the chromosome, since the selection coefficient (s) is much larger than the mutation rate (ν).

I present here some of the results of my preliminary simulation studies. Since the details will be published elsewhere, only the parameters and the results are given. Two cases have been studied: (1) the population size (N) = 50 (haploid), $n = 10$, $\nu = 0.004$ and $k = 1$, (2) $N = 25$, $n = 5$, $\nu = 0.002$ and $k = 1$. Each case was run with and without selection ($s = 0$ or 0.5), and with and without inter-chromosomal crossover (total of 0 or 25 recombinations per generation in case 1 and 0 or 12 recombinations in case 2). Table 1 shows the results (average values of 101–350th generations). It can be seen that the present formulation holds without inter-chromosomal crossover. The average clonality decreases considerably with inter-chromosomal crossover though selection works whether there is inter-chromosomal crossover or not.

The present model is overly simple in another respect since it assumes that selection is solely dependent on the clonality and also that the number of gene units in a family is fixed. Actually,

Table 1 Average and variance of clonality observed in simulation studies

Population size (N)	No. of units (n)	Selection coefficient (s)	Total no. of inter-chromosomal crossovers per generation	Observed mean clonality	Observed variance of clonality
50	10	0	0	0.754 (0.714)*	0.048 (0.050)†
			25	0.444	0.021
		0.5	0	0.433	0.016
			25	0.295	0.009
		0	0	0.949 (0.952)*	0.014 (0.015)†
			12	0.781	0.028
25	5	0.5	0	0.710	0.034
			12	0.604	0.029

*Calculated by the formula (5).

†Calculated by the formula (11).

the selection is not only a function of clonality but also of the combinations of mutant genes, and also the number of gene units should be a random variable and subject to natural selection. In addition, the additive selection based on clonality is too simple. In principle, the fitness of a heterozygote could be assigned by measuring the clonality in the two chromosomes, which may differ from the additive effect. The more realistic approach awaits future analyses taking these assumptions into account. The important differences of the present approach from the traditional evolutionary theory are that the mutant genes can spread via coincidental evolution and that the gene family rather than individual mutant is considered as the unit of selection. Furthermore, in the present model, the genetic variation for natural selection to operate on (V_c) is generated by mutation and crossing-over, yet the total genetic variation including within-chromosome variance ($1-C$) may be kept mainly by selection. In fact, the antibody combining sites of immunoglobulins are hypervariable (see ref. 11 for review), suggesting that the kind of selection studied here is important. If multigene families are fairly common phenomena as speculated by Hood *et al.*¹, some similar type of selection may be operating in guiding some of the important quantitative genetic variations for the adaptation and evolution of higher organisms.

I thank Drs M. Kimura and A. Robertson for discussions and suggestions.

Loss of ability to kill *Fasciola hepatica* in sensitised rats

RATS infected orally with metacercariae of the liver fluke *Fasciola hepatica* develop a partial resistance to oral challenge. This resistance occurs when the sensitising flukes have reached and are living in the bile ducts; resistance also develops if the sensitising infection is terminated by anthelmintics whilst the flukes are migrating through the liver parenchyma¹⁻³. Living adult flukes can be successfully

transplanted into the peritoneal cavity of rats^{4,5}, but if the rats have been infected with *F. hepatica* metacercariae approximately 10 weeks previously, the flukes transferred into the peritoneal cavity will be killed^{2,6}. We report here that although a marked resistance to intraperitoneal challenge with adult flukes develops as early as 2 weeks after oral infection with normal metacercariae, rats which have been infected 12 months previously, and which still have living adult flukes present in their bile ducts have lost this immunity. If rats with long-standing fluke infections in their bile ducts are reinfected with metacercariae, however, the ability of the rats to kill the challenge flukes is restored.

Adult flukes, obtained aseptically from the bile ducts of donor goats, were kept individually until transfer at 37 °C in medium 199 containing 10% foetal calf serum and antibiotics⁵. Female PVG rats (Piebald Virol Glaxo) were each infected with 20 metacercariae. The faeces of rats with long-standing infections were examined for fluke eggs as previous work⁷ had shown that many rats eliminate a primary infection after 7-8 months. Control and sensitised rats received three living adult flukes intraperitoneally. The rats were killed 7 d later and flukes were recovered and examined.

The results given in Table 1 show the effect of the duration of a primary infection on subsequent challenge. Rats sensitised for 1 week only did not kill the adult

Table 1 The effect of duration of infection on subsequent challenge

Infection and duration	No. of rats	Total no. of flukes found at necropsy		
		Dead	Alive	% Dead
None (Control 1)	6	0	18	0
None (Control 2)	6	2	16	11
1 week	5	1	14	6
2 weeks	5	13	2	86
3 weeks	6	13	5	72
4 weeks	6	17	1	98
6 weeks	6	15	3	83
12 months	6(-ve)*	0	18	0
12 months	6(+ve)*	3	15	17
None (old rats) control	5	0	15	0

Each rat was challenged with three living adult flukes placed in the body cavity. These are the flukes recovered at post mortem examination and referred to in the Table. Two control groups (1 and 2) are shown as the Table summarises two experiments. The group of old control rats was included to show that surgically transferred flukes behave normally in old rats.

* (+ve) or (-ve) indicates the presence or absence of flukes in bile ducts from primary infection.

Table 2 Effect of reinfection on subsequent challenge

Age of primary infection	No. of rats	Flukes in bile ducts	Postmortem examination		% Dead
			No. of challenge flukes Dead	Alive	
12 months	7(+ve)	present	17	4	84
12 months	7(-ve)	absent	19	2	94
None (control) (old rats)	6	—	18	0	100

The first group of rats (+ve) showed fluke eggs individually in their faeces whereas the second group were negative. These two groups of rats together with uninfected controls were infected with 20 metacercariae orally and all rats challenged 3 weeks later with three adult flukes. At post mortem examination the flukes found in the bile ducts were from the primary infection. All rats showed fluke tracts on their livers.

challenge flukes placed in the body cavity, but by two weeks after sensitisation this ability to kill the challenge had fully developed and was also seen to be operative at 3, 4, and 6 weeks after sensitisation. In contrast, rats which had been infected 12 months previously had lost the ability to kill challenge flukes in spite of the continued presence of adult flukes of the primary infection in the bile ducts.

Table 2 demonstrates the re-infection with metacercariae restores the ability to kill flukes in rats infected 12 months previously, irrespective of whether the primary infection had been eliminated or not. In those rats in which adult flukes of the primary infection were still living in the bile ducts (+ve rats in Table 2), the new sensitising secondary infection of 3 weeks duration was also alive and actively migrating in the liver parenchyma, whereas the challenge flukes were killed in the body cavity.

The ability of rats to kill the adult challenge flukes was apparently dependent on a recent migration of immature flukes in the liver parenchyma. It has been suggested that the duration of liver migration (10–11 d) in mice is responsible for the stimulation of acquired immunity⁸. Rats in which flukes have reached the bile ducts progressively lose their ability to kill challenge flukes. Perhaps the adult flukes living in the bile duct either do not produce the right antigenic stimulus, or do not present it in the right situation for processing. Alternatively, the migratory phase in the liver may produce an inflammatory response of short duration acting in the body cavity. Preliminary histological observations on the cysts surrounding challenge flukes in sensitised animals showed an intense infiltration of eosinophils into the walls and lumen of the cysts.

Although it is dangerous to extrapolate from a small animal model system, it is possible that the situation seen in the field whereby ruminants such as sheep or goats with long standing fluke infections are susceptible to re-infection is similar to the phenomenon reported here.

Microcalorimetry of isolated mammalian cells

Using microcalorimetry^{1,2}, we have measured the heat evolved by isolated cells of brown adipose tissue (BAT). This tissue generates heat in newborn and cold-adapted mammals and in hibernators during arousal from hibernation and during cold stress^{3–5}. The method can be applied generally in work with, for example, mitochondria and isolated cells and has, especially in studies of thermogenesis,

the advantage of measuring the gross calorific output of all processes in the cell. Our results, compared with others obtained by routine methods, show that it is an oversimplification to consider BAT as the major source of heat during arousal.

Noradrenaline (NA) is the physiological stimulator of thermogenesis in BAT, and the brown adipocytes responded calorigenically (Fig. 1) to stimulation with NA in accordance with the patterns known from polarographic studies. NA-induced oxygen consumption proceeds faster and for a longer time if the buffer is bubbled with 5% CO₂ in air, rather than with air⁶, and this is reflected in our measurements of calorific output (Fig. 1). Because oleate stimulates oxygen consumption in adipocytes, possibly by mimicking the action of the hormone-sensitive lipase⁷, we have investigated the calorogenic effect of 35 μ M oleate. The response of the cells paralleled those obtained by polarographic studies (not shown).

Table 1 Ratios of heat evolution to oxygen consumption

Theoretical	
NADH oxidation to water	258
Succinate oxidation to water and fumarate	151
Palmitate, stearate or oleate combustion to water and CO ₂	218
Acetate combustion to water and CO ₂	219
Palmitate oxidation to acetate and CO ₂	219
Experimental	
1 μ M NE-stimulated cells	243

The ratios are expressed as kJ per mol of oxygen. The theoretical values are calculated from¹⁴. The experimental value is calculated from the steady state 5 min after stimulation. (Ivlevs oxycalorific coefficient¹⁵ amounts to 226 kJ per mol of oxygen.)

The heat evolved by maximal NA-stimulation at 37 °C was 820 μ W per 10⁶ cells, and heat evolution continued for at least 50 min. This is five times greater (using our estimate of 10⁶ cells per g wet weight) than reported in the only other calorimetric study, made with tissue slices⁹. Based on these figures the 2 g of BAT found in a hamster weighing 100 g (with the same heat capacity as water) would be able to warm the whole hamster less than 1 °C per h (neglecting in the calculation heat loss to the surroundings). This should be contrasted to the fact that hibernating hamsters arouse, even in a cold environment, in 2 h, that is, they increase their body temperature 15 °C per h, and even though some shivering takes place in the last phase, BAT itself is clearly not able to deliver a substantial amount of the heat needed. Furthermore, our experiments were carried out at 37 °C. The heating capacity of BAT in a hibernating animal with lowered body temperature would be even less. To illustrate this we compared the NA-evoked oxygen consumption in cells at 37 °C with that at lower temperatures and found it to be decreased to 67% at 27 °C, to be less than 10% at 15 °C and to be immeasurable at 7 °C, the body temperature of hibernating hamsters.

Fig. 1 Comparison between polarographic and calorimetric responses of brown adipocytes to stimulation with NA. Brown adipocytes were prepared as described before⁶ by collagenase treatment of pooled BAT from warm-adapted hamster. (In contrast to non-hibernators such as the rat, hamsters and other hibernators retain thermogenic BAT even in a warm environment.) Oxygen consumption was measured polarographically⁷ at 37 °C with a Clark oxygen electrode. Heat evolution was measured in a LKB 2107 batch microcalorimeter. The sample vessel consisted of a large compartment (4 ml) containing the cell suspension and a small compartment (1 ml) containing NA. The reference vessel contained cell suspension in the large compartment but only buffer in the other. The temperature of the thermostat was 37 °C. After equilibration, the contents of the vessels were mixed by rotation, and the difference in heat output between stimulated and unstimulated (basal respiring) cells was monitored on a potentiometric recorder. The instrument was calibrated by applying a known current through a known internal resistance. The response time of the calorimeter was in the order of tens of seconds. Control experiments showed that an unlimited supply of oxygen to the cells was ensured if the vessels were rotated every fifth minute, enabling the oxygen in the vessels to dissolve in the buffer. This was done in all experiments, giving rise to the distortions on the figures. Heat of dilution of agents has been subtracted from the curves where necessary. All cell suspensions were at 100,000 per ml in modified⁸ Krebs-Ringer phosphate buffer (unless otherwise stated the buffer was bubbled before the experiments with 5% CO₂ in air). NA was added to a final concentration of 1 μM for maximal stimulation.

Heat production is generally assumed to be proportional to oxygen consumption, but the heat produced per oxygen molecule used varies in different processes, for example, glycolysis and oxygenase reactions. Calculations¹⁰ of mitochondrial bioenergetics demonstrate a very high efficiency for formation of ATP, up to 96% energy conservation. If the ATP formed is not immediately hydrolysed in a process where the energy is not conserved, the ratio of heat: oxygen will be low. Thus estimation of heat evolution from oxygen consumption could be misleading, and we have therefore measured directly the caloric output and compared it with oxygen consumption.

Table 1 shows the calculated and measured ratios of heat evolution to oxygen consumption. The values are consistent with expectation. If CO₂ was omitted the ratio was not affected. This method does not enable us to distinguish between partial and total combustion of fatty acids^{11,12}. We find, as did Peakin¹³, that respirometry is a satisfactory method to estimate heat production.

To justify the use of isolated cells or mitochondria as model systems for the elucidation of the functions of BAT *in vivo*, we tabulated data from various laboratories as well as from different animals (Table 2). As conversion factors we used 10⁸ cells and 130 mg of mitochondrial protein per g of BAT (wet weight), obtained from morphometric studies, cytochrome oxidase measurements and protein determinations (personal communication from T. Barnard and B. Pettersson). We found a good correlation between systems. Earlier failures^{16,17} to obtain a satisfying oxidative capacity of BAT mitochondria have been due to the use of an 'unphysiological' substrate for mitochondria (2-oxo-glutarate instead of fatty acids). Only in the case of glucose uptake did we find a discordance, and we offer two explanations for this: (1) glucose permease is destroyed during cell preparation by the crude collagenase, known to have protease activity, and (2) the value from the whole animal is calculated as arteriovenous difference. The endothelium, the nerve endings and the mast cells—perhaps 10% of the tissue altogether—may utilise most of the glucose, the adipocytes using mainly fatty acids for their basal metabolism.

In newborn rabbits²⁸ and lambs²⁹ BAT accounts for most of the increase in oxygen consumption during cold-stress or infusion of NA. In cold-adapted rats it is suggested to account for 8% of the increased oxygen consumption³⁰. No direct measurements have been made on hibernators. Jansky³¹ has estimated the importance of BAT during arousal from hibernation (in bats). He measured the oxidative capacity of cytochrome aa₃ and concluded that BAT could consume 25% of the total oxygen used during arousal. This is a maximum estimate—cytochrome aa₃ is presumably not the rate-limiting enzyme in fatty acid

Table 2 Comparison between quantitative results from investigations on different organisation levels

	Heat production experimental (W)	Heat production calculated from oxygen consumption (W)	Oxygen consumption (μmol min ⁻¹)	Fatty acid release (μmol min ⁻¹)	Fatty acid uptake (nmol min ⁻¹)	Glucose uptake (nmol min ⁻¹)
Mitochondria		0.6	182 (Hamster) ^{18*} 174 (Rat) ¹⁹ 170 (Lamb) ²⁰ 226 (Guinea pig) ²¹			
Adipocytes	0.2	0.3	100 (Hamster) ⁸	8 (Hamster) ²³	400 (Hamster) ²⁵	12 (Rat) ²⁷ 120 (Hamster) ²⁵
Whole animal	See text		100 (Rabbit) ²²	4 (Rabbit) ²⁴	240 (Rabbit) ²⁶ 770 (Rabbit) ²⁴	3,000 (Rabbit) ²⁴

All values are related to 2 g of BAT as found in a newborn rabbit or an adult hamster (both 100 g). As mitochondria are traditionally examined at 23 °C, the values here have been corrected to 37 °C by a factor 2.8, obtained from experiments with hamster mitochondria (our unpublished observation and ref. 11).

*All uncoupled palmitoyl carnitine oxidation in the presence of malate.

combustion.

Our calorimetric measurements indicate that BAT has a low thermogenic capacity when compared with the heat needed to arouse a torpid hamster. Because of the general accordance between data obtained from studies *in situ* and in isolated cells, we believe that the cells elicited their full thermogenic capacity, and the opinion that BAT has thermogenesis as its primary function requires modification. Several suggestions have been made, for example, that the heat produced primarily warms the central nervous system¹ or that BAT also has an endocrine function³². During cold-stress the fat depots in BAT are emptied rapidly in both warm-adapted²⁵ and cold-adapted hamsters (our unpublished observations). As brown adipocytes are efficient in export of fatty acids^{23,24} which themselves have been shown to increase oxygen consumption in, for example, heart tissue³³, BAT may generate the main part of 'its' heat in other tissues where fatty acids liberated from BAT are combusted during cold stress. We have confirmed earlier studies³⁴ showing that in hamsters BAT does not lose any of its stored fat during arousal from hibernation. Because of these findings, and because of the relatively low calorific output reported here the direct role of BAT during arousal in the hamster must be questioned.

We thank LKB-Products for the loan of the LKB microcalorimeter and Ms Ulla-Birgitta Andersson and Ms Barbro Kyte for assistance. This work was supported by a grant from the Swedish Natural Science Research Council.

Lymphocyte migration into cell-mediated immune lesions is inhibited by trypsin

THE lymph nodes and the white pulp of the spleen are major sites into which lymphocytes migrate from the blood and each organ is equally selective in that other blood cells are efficiently excluded^{1,2}. It might be expected that the same mechanism for discriminating between lymphocytes and other cells would have evolved in the spleen and lymph nodes, but the entry of lymphocytes into each of these organs can be distinguished in two ways. First, the histological appearance of the vascular endothelium across which lymphocytes migrate is dissimilar^{1,3} and second, the capacity of lymphocytes to migrate from the blood into lymph nodes is reduced by brief exposure *in vitro* to low concentrations of trypsin, but migration of the same population into the spleen is barely affected⁴. Lymphocytes are not irreversibly damaged by trypsin because they regain their capacity both *in vivo* and *in vitro*⁵ to localise in lymph nodes. The reduced numbers in lymph nodes is not a consequence of increased localisation of trypsinised lymphocytes elsewhere, as is testified by perfusing trypsinised lymphocytes through an isolated lymph node⁶ and also by measuring the numbers of trypsinised lymphocytes in the blood after intravenous injection^{6,7}. For several hours the concentration of treated cells in the blood was about 1.4 times that of control cells. This excess was attributed to the failure of trypsinised cells to enter lymph nodes⁶. We have extended these observations by comparing the capacity of trypsinised and control lymphocytes to migrate from the blood into several non-lymphoid tissues including sites of inflammation. Exposure of lymphocytes to trypsin not only exerts a differential effect on lymph node and spleen localisation, it also differentiates the mechanism by which lymphocytes migrate in small numbers into normal skin and other non-lymphoid tissues (trypsin resistant) from that responsible for the migration of increased numbers of lymphocytes into cell-mediated immune (CMI) lesions in the skin (trypsin sensitive).

To determine whether the differential effect of trypsin on lymph-node and spleen localisation is merely a quantitative effect, lymphocytes obtained by thoracic duct cannulation⁸ of AO rats were labelled *in vitro* with either ³H-uridine or ¹⁴C-uridine⁸. The ³H-labelled lymphocytes were exposed *in vitro* to graded doses of trypsin in phosphate-buffered saline (PBS), washed, combined with the ¹⁴C-labelled cells as a reference population and injected into syngeneic recipients. No reduction of spleen localisation was found with a concentration of trypsin 125 times greater than that needed to inhibit lymph-node localisation by 50% (Table 1). The standard concentration of trypsin previously used (0.02 mg ml⁻¹) (refs 4 and 6) reduced lymph-node localisation to 10% of untreated cells at 1 h after injection and increasing the dose by 5- or 25-fold had little additional effect on either the deficit in the lymph nodes or the excess in the blood. The distribution of trypsinised cells at 24 h resembled that of control cells and only at the highest concentrations was there evidence of loss of a minority of the cells. There thus seems to be a qualitative difference in the trypsin sensitivity of lymphocyte migration into the spleen and lymph nodes.

Lymphocytes also migrate from the blood into non-lymphoid tissues such as skin, albeit in much smaller numbers than into secondary lymphoid organs and the rate of migration is increased into sites of CMI (refs 9-12). We investigated whether migration into non-lymphoid tissue resembled migration into lymph nodes in being trypsin sensitive and whether trypsin treatment could distinguish between migration into normal and inflamed skin.

Lymphocytes were obtained by thoracic duct cannulation

Table 1 Effect of graded concentrations of trypsin on lymphocyte localisation in organs of recipients*Ratios of ^3H (associated with trypsinised cells) to ^{14}C (control cells)†

Time after injection	Organ	Concentration of trypsin (mg ml ⁻¹)			
		0.5	0.1	0.02	0.004
1 h	Lymph nodes	0.07	0.07	0.10	0.51
	Spleen	0.99	0.96	1.02	1.02
	Blood	1.47	1.46	1.32	1.17
	Lung	1.68	1.04	1.12	0.98
	Liver	1.35	1.22	1.01	0.86
	Gut	0.72	0.91	1.02	0.96
	Bone marrow	0.78	0.97	1.07	0.98
	Lymph nodes	0.72	0.76	0.89	0.89
	Spleen	1.18	1.06	1.05	0.92
	Blood	0.69	0.75	0.82	0.92
24 h	Lung	0.82	0.88	0.88	0.95
	Liver	1.15	0.91	1.07	1.04
	Gut	0.86	0.78	1.01	0.94
	Bone marrow	0.79	0.84	0.88	0.78

*Lymphocytes exposed to trypsin *in vitro* for 10 min.†All ratios are standardised so that $^3\text{H}/^{14}\text{C}$ ratio in the injection sample = 1.00. A supplementary group of recipients received ^3H -labelled cells (untreated) and ^{14}C -labelled cells (untreated). As expected the $^3\text{H}/^{14}\text{C}$ ratio generally fell in the range of 0.90–1.10 indicating an even distribution. In the Table, a ratio of less than 0.80 indicates a significant deficit of trypsinised cells and a ratio of more than 1.20 a significant surplus.

of inbred AS or (PVG/c×DA) F_1 rats⁸. They were radioactively labelled *in vitro* by incubation with ^{51}Cr -sodium chromate at $10 \mu\text{Ci ml}^{-1}$. The cells were suspended in medium RPMI 1640 with 10% FCS at 37°C for 1 h. After washing, half the suspension was treated with trypsin (Boehringer) at 0.02 mg ml^{-1} for 10 min. After further washing, trypsinised and control cells were injected intravenously into separate syngeneic recipients, which were killed at 0.5, 2 or 24 h after injection. A 2-ml sample of blood was taken and the entire vasculature was perfused through an aortic cannula with a large volume of PBS. The use of ^{51}Cr as a radioactive label for lymphocytes and the perfusion procedure have been found to be the most satisfactory method of measuring lymphocyte migration into non-lymphoid tissues¹³. The spleen and the six largest superficial cervical lymph nodes were removed and also samples taken of the tissues referred to in Table 2. The specimens were weighed before radioassay in a LKB γ -counter.

Two series of experiments were performed involving recipients with contact sensitivity lesions and adjuvant granulomata. Contact sensitivity was induced by painting an area of ventral abdominal skin with 0.1 ml of 5% DNCB in alcohol. Twelve days later a site on the back was painted

with a challenge dose of DNCB (0.1 ml of 0.5%). As control sites, primary application of two other contact sensitising agents, TNCB (0.1 ml of 1%) and oxazolone (0.1 ml of 0.5%), and croton oil (0.1 ml of 10%) were applied simultaneously to different areas of dorsal skin 24 h before the injection of labelled lymphocytes. In other recipients adjuvant granulomata had been produced by intradermal injection 21 d previously of 0.1 ml of Freund's complete adjuvant (Difco) emulsified with PBS.

The localisation of lymphocytes in normal skin was clearly not impaired by trypsin; radioactivity associated with trypsinised lymphocytes found in the skin soon after injection was equal to or slightly greater than radioactivity associated with untreated cells (Tables 2, 3) possibly reflecting the marginally higher numbers in the blood. It was confirmed that the migration of lymphocytes into the spleen and liver is unimpaired by trypsin treatment especially when compared with the blood level. Similarly, migration into muscle (Table 2), brain and ovary were almost equal for trypsinised and control cells suggesting that migration of lymphocytes into non-lymphoid tissues in general may be trypsin resistant. By contrast, migration into lymph nodes was reduced by trypsin to 1–2% of control values at 30 min or 2 h after injection (Table 2).

The most striking result was that trypsin treatment impaired the capacity of lymphocytes to migrate into sites of CMI in the skin (Tables 2 and 3). In the case of the DNCB lesion, the early localisation (0.5 h, 2 h) of untreated lymphocytes was increased to 1.5–2.5 times that of normal skin or sites painted with TNCB or oxazolone (Table 2). Although small, this increase was significant and occurred consistently in five other series of experiments on the migration of lymphocytes into DNCB lesions. The localisation of trypsinised cells was significantly less than that of control cells in DNCB lesions and was nearly the same as in normal skin. Thus, if it is acceptable to regard the values for normal skin as a baseline, the data indicate that very few if any trypsinised lymphocytes entered the skin as a result of DNCB challenge. The results followed the same pattern for the granuloma (Table 3) and were more emphatic: 2–3 times as many untreated lymphocytes were present in the lesions as were present in normal skin at 30 min and 2 h but equal numbers of trypsinised lymphocytes were present in the granuloma and in normal skin at each of the early intervals.

We conclude that mechanisms of selective lymphocyte migration can be placed into two categories. The first, which is trypsin resistant, operates in the spleen and non-lymphoid tissues and the second is trypsin sensitive and operates in lymph nodes and sites of CMI. Non-immune chronic inflammatory lesions have not been investigated.

It is possible that trypsin distinguishes two subsets of thoracic duct lymphocytes rather than two mechanisms of

selective migration which are properties of different endothelia. In particular, could the inhibitory effect of trypsin on migration into sites of CMI be exerted solely on large lymphocytes which are known to migrate especially well into sites of inflammation¹⁰⁻¹²? The present results do not completely exclude this but we feel it is likely that trypsin does impair small lymphocyte migration into CMI lesions for two reasons. First, small lymphocytes do migrate into CMI lesions in increased numbers as has been supported by cannulation of the lymphatic draining an adjuvant granuloma in sheep⁹ and selectively labelling small lymphocytes with ^3H -thymidine *in vivo* and detecting an increased localisation in DNCB lesions (G.H.R., unpublished). The effect of trypsin in preventing the increased localisation in CMI lesions was complete within the limits of detection (Tables 2, 3) and so the migration of both small and large lymphocytes was probably impaired. Second, large lymphocytes not only migrate preferentially into inflamed tissues but seem to be superior in migrating into non-lymphoid tissues in physiological conditions. This was suggested by injecting alternately labelled large and small lymphocytes and examining the cells migrating into normal rat skin¹³ and non-inflamed peritoneal cavity (O. Braendstrup and O. Werdelin, unpublished). In conclusion, although it is possible that trypsin may affect lymphocyte subsets differentially, it seems improbable that this factor could wholly explain the present results; at least some lymphocytes are capable of leaving the blood by either of two mechanisms.

In an adjuvant granuloma in sheep, the increased flux of lymphocytes was associated with a change in the appearance of the endothelium of small venules, which came to resemble the morphologically distinct high-walled endothelium in lymph nodes⁹. This is consistent with the notion that a granuloma accepts an increased influx of lymphocytes by the same mechanism as lymph nodes accept more lymphocytes from the blood than do non-lymphoid tissues. Of the two examples of a trypsin-sensitive mechanism of selective lymphocyte migration, the endothelial change in CMI may have appeared earlier in evolution since histologically well developed lymph nodes are confined to mammals. Possibly lymph nodes developed when the endothelium of small vessels in certain regions displayed as a permanent feature an adaptation which was previously unique to sites of chronic inflammation. Other features of lymph node organisation may have ensued as a result of the vascular change.

Steroid-nucleosides possible novel agents for cancer chemotherapy

THE major classes of anti-cancer chemotherapeutic drugs include alkylating agents, 'anti-metabolites of nucleic acids, steroid hormones and antibiotics'. Because of the lack of specificity of anti-tumour agents, attempts have been made to increase their specificity and cell-penetrating properties by coupling them to steroid hormones^{2,3}. In particular, steroidal alkylating agents exhibit carcinostatic properties if used in combination with other modes of therapy⁴. We have prepared a novel class of agents by coupling steroids with naturally occurring purines and pyrimidines by way of a C-N linkage. The structures are unique in that they may be regarded as analogues both of steroid hormones and of 'nucleosides' in which the sugar has been replaced. Accordingly, we may expect their steroid moiety to provide target specificity, while their nucleoside characteristics may result in interference at the DNA level to give the desired anti-tumour activity. Preliminary studies on the effect of steroid-nucleosides on the lifespan of tumour-bearing animals show that selectively coupled products exhibit anti-tumour activity.

The chemical combination of cholesterol, pregnenolone, progesterone and cortisone with various nucleoside bases and imidazole-derived heterocyclic compounds was accomplished by adapting general methods used in nucleoside synthesis⁵. Briefly, the appropriate bromosteroid was reacted with the persilylated heterocyclic in the presence of an HgO/HgBr_2 catalyst to give a C-N linkage. (Details of these preparations will be presented elsewhere.)

A number of our newly-synthesised steroid-nucleosides were tested for acute toxicity on CD-1 outbred albino female mice at 100 and 200 mg kg⁻¹ single dose levels (intra-peritoneally, 0.2 ml sesame oil). None of these compounds proved to be toxic at these levels, with the exception of the 3 α -imidazole derivative of pregnenolone. This compound induced convulsions within 1 h at the lower concentration, and death within 12 h at the higher dose. A series of thymine and uracil derivatives were tested for anti-tumour activities on Fisher 344/CRBL female rats bearing the 13762 mammary adenocarcinoma. This tumour is sensitive to oestrogens and androgens. Progesterone does not significantly inhibit tumour growth⁶, however, even at

dose levels 15 times higher than those used in our screening (D. J. Taylor, personal communication). Accordingly, it is unlikely that any anti-tumour effects of our steroid-nucleosides could result from breakdown of the drugs to give the free steroid. The compounds selected for testing included the N_1 -thymine derivatives at the 3 α -position of cholesterol (1), the 3 α - and 3 β -positions of pregnenolone (2) and (3), and the 21-position of progesterone (4); and the N_1 - and N_3 -uracil and N_1 -5-fluorouracil derivatives at the 3 α -position of pregnenolone (5), (6) and (7). The effect on the lifespan of the animals is summarised in Table 1. Control animals treated with sesame oil alone developed large tumour masses and had a mean survival of 29.1 d. In the thymine series ((1)-(4)) where the compounds differed only in the steroid moiety, the 21-progesterone analogue (4) increased the mean survival time of the host to 45.7 d, thus exhibiting marked anti-tumour activity. The remaining compounds of this series showed only minimal effect. The 3 α -pregnenolone-uracil compounds ((5)-(7)) differed in the site of attachment to the base, and although the N_1 -derivatives of uracil and of 5-fluorouracil were inactive, the N_3 -derivative of uracil (6) increased the mean survival time considerably, to 49.5 d. Treatment with 3 α -imidazolepregnenolone (8) also prolonged the survival to 40.8 d.

8	Imidazole-pregnenolone		3 α (N_1)	40.8($\pm$ 2.2)	0.001
0	Control			29.6($\pm$ 1.8)	—

Treatment was started 24 h after animals were given subcutaneous tumour grafts. The agents were administered subcutaneously in sesame oil (10 mg ml⁻¹) at a dose of 10 mg kg⁻¹ on alternate days for a total period of 18 d. Groups of 10 animals were used (except for compound (4) which involved seven animals). Of the group treated with compound (6), four animals did not develop a palpable tumour. These four survivors were not considered in the determination of the standard error and significance. The level of significance (P) was evaluated using Student's *t* test. Progesterone itself does not affect this tumour⁶.

The data suggest that greater anti-tumour activity results from an N_3 -substitution of the pyrimidine and from the use of steroids with higher hormonal activity. Most conventional drugs have undesirable side effects due to their inhibiting effect on both normal and tumour cell proliferation, and must be given at high concentration to eradicate all growing tumour cells. Our derivatives are less likely to have adverse side effects, as their decomposition products are natural steroids and nucleoside bases. Based on these encouraging results and the above considerations we are pursuing a program of selective synthesis and more detailed biological evaluation of steroid-nucleosides.

We thank Dr A. E. Bogden, Mason Research Institute, Worcester, Massachusetts and the NIH, Bethesda, Maryland for providing the 13762 mammary tumour and Drs R. Pageau and G. J. Fisher for their critical evaluation of the

Glucocorticoid receptors and glucocorticoid sensitivity of mitogen stimulated and unstimulated human lymphocytes

GLUCOCORTICOIDS exert widespread suppressive effects on lymphocytes of most species^{1,2}. Sensitivity to the hormones is thought to vary with the state of lymphocyte maturation and differentiation. Immature thymic lymphocytes, for example, are more sensitive than mature thymic-dependent lymphocytes^{1,3}. Furthermore, *in vitro* studies have suggested that glucocorticoid sensitivity varies with the state of mitogen or antigen-induced activation. Nowell⁴ observed that prednisolone-21-phosphate reduced the number of mitoses induced in human peripheral blood lymphocytes by phytohaemagglutinin (PHA), and noted that this inhibition required the presence of glucocorticoids during the first 24 h of exposure to PHA. When glucocorticoids were added 48 h after PHA, a time when mitoses had not yet appeared, they had no effect on the number of mitoses measured 2 d later. Tormey *et al.*⁵ extended these results to show that prednisolone-21-phosphate inhibited incorporation of radiolabelled thymidine and cytidine into PHA-stimulated lymphocytes, and found that delayed addition of steroid resulted in diminished inhibition.

These and similar observations have led to the generally accepted view, basic to the application of glucocorticoids as immunosuppressants, that glucocorticoid sensitivity varies with the state of immunologic activation of the cell. Lymphocytes are thought to be insensitive until they are stimulated by specific antigen or mitogen, which induces an early glucocorticoid-sensitive phase before resistance again supervenes with full morphologic blast transformation and mitosis^{1,6}.

Because of the central role of glucocorticoid receptors in the action of glucocorticoids on lymphoid and other tissues, we have measured simultaneously the inhibitory effects of glucocorticoids on metabolic parameters and the number of glucocorticoid receptors in cultured human lymphocytes undergoing transformation. Our results indicate that, contrary to widespread assumption, lymphocytes are sensitive to metabolic inhibition regardless of their state of activation, and that furthermore, blast transformation is associated with a striking increase in the number of receptor sites per cell.

Human lymphocytes were cultured and assayed with dexamethasone (DX) for nuclear glucocorticoid receptor sites at 37 °C as described in the legend to Fig. 1. In this experiment, following addition of concanavalin A (Con A) to cultured lymphocytes, a sixfold increase in receptor sites per cell was noted by 24 h, with maximum levels occurring before 48 h (top curve, Fig. 1). By 6 d, levels returned to

Fig. 1 Nuclear dexamethasone binding in human peripheral lymphocytes after Con A stimulation. Mononuclear cells were obtained from defibrinated fresh human blood by discontinuous density gradient separation over Ficoll-Hypaque¹⁰. Monocytes were removed by incubation on plastic for 18 h leaving a cell population consisting of 94% or more lymphocytes. Cells were cultured at 1×10^6 per ml in RPMI 1640 with 50 units per ml penicillin, $50 \mu\text{g ml}^{-1}$ streptomycin, 300 mM glutamine and 10% foetal calf serum. At time zero, $20 \mu\text{g ml}^{-1}$ con A was added. At the indicated times, aliquots containing 5×10^7 cells were removed and incubated at 37°C for 20 minutes (sufficient time to approach a steady state) with ^3H -DX (New England Nuclear; $22.6 \text{ Ci mmol}^{-1}$), at seven concentrations from $2 \times 10^{-7} \text{ M}$ to $5 \times 10^{-10} \text{ M}$. Nuclear pellets were obtained by lysis for measuring nuclear binding as described previously⁷. Results were plotted according to the method of Scatchard¹¹ to obtain estimates of the association constant and concentration of nuclear binding sites. Cell protein content was determined by the method of Lowry¹² using the supernatant after a freeze-thaw, hypotonic lysis, and cell volumes were calculated from the cell counts and the cytocrit (obtained by a micro haematocrit method) of the original cell suspension. Viability was determined from the proportion of cells excluding Trypan blue and was greater than 90% at the time of the assay. The 100% values are those for time equal to 0 h. ●, Sites per cell, 100% = 4,470. Δ, Sites per μg protein, 100% = 2.2×10^8 . ○, Moles per l cell volume, 100% = 1.5×10^{-8} .

approximately twice the initial value. Similar, but less pronounced changes were seen when results were expressed as binding sites per μg protein or per l cell volume (lower curves, Fig. 1). The exact time course of these changes was somewhat variable. In some experiments the peak number of binding sites did not occur until 72 h (for example Fig. 2). No significant changes were observed in the association constants, which averaged $1.4 \times 10^8 \text{ M}^{-1}$. Cytoplasmic receptor sites (data not shown), measured as previously described⁷, showed similar changes in number.

In separate experiments with cells from ten individuals (Table 1) we found a two-fourfold increase in DX binding sites per cell over unstimulated controls. This increase occurred regardless of the mitogenic stimulus. The controls showed no significant change in glucocorticoid binding.

Note that there was considerable variability in the receptor content of unstimulated cells. Cytoplasmic-to-nuclear translocation⁷ of the steroid receptor complex was found to take place normally in both mitogen-stimulated and control lymphocytes. When incubated with DX at 3°C , most of the binding was restricted to the cytoplasm, but after warming the cells to 37°C for 20 min, 50–80% of the complexes became nuclear bound. Cortisol, cortisone and corticosterone at 10^{-6} M competed significantly for binding of DX in both stimulated and unstimulated lymphocytes. Cortisone, testosterone, estradiol and progesterone at 10^{-6} M did not show significant competition. The time course of nuclear binding at 37°C reached a steady state after 20 min of exposure to DX for both control and con A-stimulated lymphocytes. Thus the DX-binding substances in mitogen-stimulated lymphocytes behave in all respects like glucocorticoid receptors in normal lymphocytes⁷, differing from those in the unstimulated cells only by their greater number.

The sensitivity of the Con A-stimulated lymphocytes to metabolic inhibition by DX at various times after activation is shown in Fig. 2. DX (10^{-7} M) was added after 24, 48 and 72 h of culture in the presence of con A. After 6 and 19 h exposure to DX, the incorporation of tritiated thymidine (^3H -Tdr) and tritiated uridine (^3H -Ur) was measured. The number of DX binding sites after exposure to con A was determined on separate aliquots, as described in Fig. 1. DX produced significant suppression of the incorporation of both the isotopes, but did not alter viable cell numbers. The degree of suppression of isotope incorporation did not vary significantly with time of exposure to Con A was determined on separate aliquots, as described increased fourfold during the culture period. We have also conducted these experiments with 10^{-6} , 10^{-8} and 10^{-9} M DX, with essentially the same results as with 10^{-7} M , except that suppression was dose-dependent and marginal with 10^{-9} M .

Similar studies (results not shown) were performed using unstimulated human lymphocytes placed into culture with and without DX (10^{-10} to 10^{-6} M). In five experiments there was a dose-dependent suppression of ^3H -Ur and ^{14}C -leucine incorporation of similar magnitude to the suppression shown in Fig. 2, measured after 24, 48 and 72 h of culture.

DX decreased glucose uptake by approximately the same absolute amount in both con A-stimulated and unstimulated lymphocytes (Fig. 3). The relative decrease was less for the stimulated cells, because of their higher base level of glucose uptake.

These studies demonstrate that mitogen stimulation leads to a marked increase in the number of glucocorticoid receptors per cell and that the cells remain sensitive to glucocorticoids. Our results do not necessarily contradict the earlier observations cited above. Previous investigators have generally measured the number of mitoses, number of blast transformed cells, or isotope incorporation at a fixed time after addition of mitogen with a varying time of exposure to glucocorticoids^{4,5}. These experimental approaches create an apparent loss of suppressive effect if the suppressive agent is added after the cells have begun to

Table 1 Effects of mitogenic stimuli on nuclear dexamethasone binding sites

Stimulus	No. of experiments	Dexamethasone binding sites per cell		
		Unstimulated	Stimulated	Stimulated/unstimulated
Con A	7	$3151 \pm 726^*$	$9,483 \pm 1,513^*$	$3.79 \pm 0.71^*$
PHA	1	1640	10,300	6.28
PWM	1	2490	6,750	2.71
MLC	2	$1,541; 4,070^\dagger$	$3,248; 11,160^\dagger$	$2.11; 2.71^\dagger$

Human lymphocytes were obtained and nuclear binding of DX determined as in the legend for Fig. 1. Cells were stimulated by incubation with con A $20 \mu\text{g ml}^{-1}$ for 3 d, PHA $10 \mu\text{g ml}^{-1}$ for 3 d and PWM (Pokeweed mitogen, GIBCO) for 5 d. Lymphocytes stimulated by mixed lymphocyte culture (MLC) (ref. 13) were obtained after 7 d incubation with allogeneic irradiated lymphocytes.

*Mean $\pm$ s.e.m.

† Values shown are ranges for the 1st and 2nd subject respectively.

proliferate in an exponential fashion. To accurately determine sensitivity, cells must be allowed to pass through blast transformation and equal numbers of cells, at the same stage of activation, must be compared with and without the suppressive agent. As we have shown using this experimental approach, human lymphocytes are equally sensitive to glucocorticoid suppression at all stages of activation, despite large increases in receptor number.

The increase in receptor number which follows mitogen stimulation may reflect variations in receptor number with phases of the cell cycle, a degree of synchronisation having been achieved by the sudden stimulation with mitogen. Cidlowski and Michaels⁸ have found that in synchronised HeLa cell cultures there is a doubling of receptor number per cell as the cells pass through late G₁, followed by return to the original number after mitosis.

The finding of an increased number of receptors in blast transformed cells, and the fact that receptor number does not relate directly to the level of glucocorticoid effect, raises practical considerations in the evaluation of glucocorticoid receptors and sensitivity of malignant lymphocytes. Lippman *et al.*⁹ have reported that lymphoblasts from patients with acute lymphoblastic leukaemia have higher levels of receptors than normal peripheral lymphocytes.

Fig. 2 Relationships between con A-induced blastogenesis, glucocorticoid receptor sites and DX suppression of tritiated thymidine and tritiated uridine incorporation. Lymphocytes (1×10^6 cells per ml) were cultured in RPMI 1640 medium, 10% autologous plasma, penicillin G, 50 units per ml, and streptomycin $50 \mu\text{g ml}^{-1}$. Con A ($20 \mu\text{g ml}^{-1}$) was added as a mitogenic stimulus. Cells were collected after 24, 48 and 72 h, and washed twice with Hanks balanced salt solution. The number of glucocorticoid receptor sites was determined as described in Fig. 1. The percentage of lymphoblastoid cells was determined on Wright-Geimsa stained Cytospin (Shandon-Southern Instruments) preparations. Cells were scored as blastoid if they were large with light staining nuclei, prominent nucleoli, and increased basophilia of the cytoplasm. Five hundred cells were counted. Aliquots of these cells (1×10^5 in triplicate) were placed into microtest-II plates (Falcon) with and without DX (10^{-7} M). Tritiated thymidine ($2 \mu\text{Ci ml}^{-1}$; 1.9 Ci mmol^{-1}) or tritiated uridine ($2 \mu\text{Ci ml}^{-1}$; 1.9 Ci mmol^{-1}) were added to the cultures from 6 to 8 and 19 to 21 h after addition of DX. Cultures were harvested on to glass fibre filters by means of a multiple automated sample harvester, washed with distilled water¹³, dried and counted in a liquid scintillation counter. Results are expressed as a percentage of isotope incorporation of cultures without dexamethasone. Brackets represent one standard deviation of per cent control. Viable cell numbers were determined by Trypan blue dye exclusion and Model B Coulter Counter before addition of DX and at the time of cell harvest. There was no significant change in cell number. The 100% values expressed as c.p.m. of isotope incorporated ± 1 s.d. were as follows: at 24 h, 6-8-h pulse $^3\text{H-Tdr} = 44 \pm 6$, $^3\text{H-Ur} = 574 \pm 35$, 19-21-h pulse $^3\text{H-Tdr} = 1109 \pm 169$, $^3\text{H-Ur} = 905 \pm 105$; at 48 h, 6-8-h pulse $^3\text{H-Tdr} = 2674 \pm 238$, $^3\text{H-Ur} = 2511 \pm 274$, 19-21-h pulse $^3\text{H-Tdr} = 2494 \pm 334$, $^3\text{H-Ur} = 1442 \pm 39$; at 72 h, 6-8-h pulse $^3\text{H-Tdr} = 2710 \pm 131$, $^3\text{H-Ur} = 1313 \pm 72$, 19-21-h pulse $^3\text{H-Tdr} = 768 \pm 123$, $^3\text{H-Ur} = 335 \pm 27$. a, Con A present for 24 h; 44% blastoid cells; 4,190 binding sites per cell. b, Con A present 48 h; 55% blastoid cells. c, Con A present 72 h; 76% blastoid cells; 16,775 binding sites per cell. Shaded bars, $^3\text{H-Tdr}$ incorporation; open bars $^3\text{H-Ur}$ incorporation.

Fig. 3 Effect of DX on glucose uptake by unstimulated and con A-stimulated human peripheral lymphocytes. Lymphocytes cultured as described for Fig. 1 in the presence and absence of con A for 3 d, were washed and resuspended at 7×10^6 per ml in Krebs's Ringer bicarbonate buffer without glucose (gassed with 5% CO_2 , 95% air). At time zero, $20 \mu\text{l}$ of the cell suspension was added to $20 \mu\text{l}$ of similar medium containing 4.4 mM glucose with varying concentrations of DX and incubated in wells of V-bottom microtitre plates (Linbro) for 5 h at 37°C with 5% CO_2 in humidified air without shaking. At the end of the incubation glucose concentration in the supernatant was measured by the glucose oxidase method (Worthington). The points represent means and vertical bars represent one standard error of four replicates. $\circ$, Unstimulated lymphocytes; $\bullet$, con A-stimulated lymphocytes.

These findings have recently been extended to include lymphoblast cells from patients with Burkitt's lymphoma and poorly differentiated lymphocytic lymphoma (G. Konior, personal communication). These investigators did not explore the glucocorticoid sensitivity of the cells as it related to receptor number, but speculated that a low receptor number might correlate with glucocorticoid insensitivity. Our results suggest that in human lymphoid cells, receptor number may correlate with the proliferative stage of the cell and may not determine glucocorticoid sensitivity.

MSA and EGF receptors on sarcoma virus transformed cells and human fibrosarcoma cells in culture

CULTURED cells transformed by murine or feline sarcoma viruses lose their ability to bind epidermal growth factor (EGF) to cell surface receptors, whereas cells transformed by DNA tumour viruses or infected with non-transforming RNA viruses show normal EGF binding¹. We demonstrate here that this sarcoma virus-dependent receptor loss is specific for EGF. The binding of a different polypeptide growth factor, multiplication stimulating activity²⁻⁴ (MSA), to its cell surface receptors was not decreased in murine and feline sarcoma virus transformed cells. In two cell lines established from human fibrosarcomas, however, MSA binding was abolished while EGF bound to the same extent as to normal human fibroblasts.

MSA is the name given to a family of polypeptides of molecular weight approximately 10,000 that is synthesised by a line of Buffalo rat liver cells in culture³⁻⁴. Like EGF and fibroblast growth factor⁵ (FGF), MSA is an efficient stimulator of cell DNA synthesis in chick embryo³, rat², 3T3 mouse⁶ and human⁷ fibroblasts in culture, and in a rat muscle cell line⁸. Specific receptors for MSA have been characterised in rat liver plasma membranes^{9,10}, and in cultures of chick embryo fibroblasts^{9,11}, adult human skin fibroblasts⁷, and a subclone of the rat liver cell line that produces MSA⁴. The binding of ¹²⁵I-labelled MSA to these receptors was inhibited only by MSA itself and by two polypeptides purified from human plasma, somatomedin A and non-suppressible insulin-like activity^{7,10,11} (NSILA-s); ¹²⁵I-MSA binding to chick embryo and human fibroblasts also was inhibited by insulin and proinsulin^{7,9,11}. Other peptide hormones and growth factors did not compete for MSA binding.

We studied MSA binding in normal rat kidney (NRK clone 2) and mink lung cells, and their sarcoma virus transformants (Table 1). The conditions of the receptor assays were those previously used to study the binding of type C

Fig. 1 ¹²⁵I-MSA binding as a function of cell number. ¹²⁵I-MSA was incubated with NRK clone 2 cells at the indicated densities per 60-mm plate. The incubations were performed as described in Table 1. The specific binding of ¹²⁵I-MSA is plotted as a function of the cell number.

viral envelope glycoprotein¹² and EGF¹ to cellular receptors, with the exception that the incubations were performed at 22 °C. Subconfluent cell monolayers were used so that both normal and transformed cells would be actively growing. MSA binding increased linearly with the number of NRK cells seeded per 60-mm Petri plate over the range 2.7 × 10⁴ to 2.4 × 10⁶ cells (Fig. 1). Although significant MSA binding can be detected with as few as 5 × 10⁴ NRK cells, most experiments were performed with 0.5–1.0 × 10⁶ cells per plate.

Normal rat and mink cells have different receptors that bind MSA or EGF selectively (Table 1, Fig. 2). The binding of ¹²⁵I-MSA was inhibited by unlabelled MSA, with 50% of the maximal inhibition by 133 ng ml⁻¹. In contrast, EGF, fibroblast growth factor, nerve growth factor, and insulin at 6.7 μg ml⁻¹ did not inhibit ¹²⁵I-MSA binding. Approximately 90% of total ¹²⁵I-MSA binding could be abolished by incubation with 3.3 μg ml⁻¹ MSA, and is referred to as specific binding. ¹²⁵I-EGF also bound specifically to normal rat and mink cells. Its binding was inhibited by EGF, but was not affected by high concentrations of MSA.

Table 1 ¹²⁵I-EGF and ¹²⁵I-MSA binding to normal and transformed cells

¹²⁵ I-labelled	Ligand	Unlabelled	Normal rat kidney cells		Normal mink lung cells		FeSV transformed
			Control	K-MSV transformed	Control	K-MSV transformed	
EGF	None		1,970	120	9,430	320	440
EGF	EGF		170	180	190	190	150
EGF	MSA		1,400	120	9,700	260	420
MSA	None		1,445	930	1,023	1,090	1,145
MSA	MSA		120	135	131	175	110
MSA	EGF		1,945	925	1,156	1,010	1,215

¹²⁵I-EGF and ¹²⁵I-MSA binding to normal cells and cells transformed by Kirsten murine sarcoma virus (K-MSV) and feline sarcoma virus (FeSV). EGF was prepared from male mouse submaxillary glands by acid extraction followed by gel filtration and DEAE-cellulose chromatography¹³. MSA was purified from the serum-free conditioned media obtained from a rat liver cell line (BRL3A) in culture^{4,5}. Purification procedures included ion exchange chromatography through Dowex-50, gel filtration chromatography on Sephadex G-50 at acid pH, and preparative acrylamide electrophoresis⁴. The iodination of EGF¹⁰ and MSA^{9,11,13} binding assay procedures and cell designations have been previously described⁴. Cells were plated in 60-mm plastic Petri dishes (Falcon) in Dulbecco's modified Eagle's medium (DMEM) containing 10% calf serum at the indicated densities: control normal rat kidney, NRK clone 2 (5 × 10⁶ cells per dish); K-MSV transformed NRK (5 × 10⁶ cells per dish); control normal mink lung cell (7 × 10⁶ cells per dish); K-MSV transformed mink lung cell (6 × 10⁶ cells per dish); and FeSV transformed mink cell (6 × 10⁶ cells per dish). After 18 h the plates were washed twice with 1.5 ml of binding buffer (DMEM containing 1 mg ml⁻¹ bovine serum albumin and 50 mM N,N-bis-(2-hydroxyethyl)-2-aminoethane-sulphonic acid (BES), pH 6.8). Binding reactions were initiated by the addition of 1.5 ml of binding buffer containing either 3 ng of ¹²⁵I-EGF (120,000 c.p.m.) or 0.4 ng of ¹²⁵I-MSA (34,200 c.p.m.) with or without 5 μg of unlabelled EGF or MSA. The dishes were incubated at 22 °C for 90 min. At the end of the incubation, the media was removed and the cell monolayers were washed four times with cold binding buffer to remove the unbound ¹²⁵I-peptides. The amount of ¹²⁵I-peptide bound to the cells was measured after lysing the cells. The radioactivity present in the lysate⁴ was determined using a Beckman LS-250 liquid scintillation counter at 60% efficiency.

Transformation of rat and mink cells with either murine or feline sarcoma viruses abolished approximately 90% of the specific EGF binding, but did not significantly reduce MSA binding (Table 1). Similar results were obtained when the binding of MSA and EGF to normal mink lung cells and mink lung cells transformed by murine sarcoma virus was compared after incubation for different times ranging from 15–180 min (Figs 3a, b). These results confirm that sarcoma virus transformation selectively perturbs the EGF receptor system.

We next asked whether the ability to bind MSA might be lost in other types of transformed cells. Mouse and rat clones transformed by the DNA viruses SV40, polyoma, and adenovirus, as well as a series of chemical carcinogen-transformed mouse clones were examined. In 17 of 18 clones tested MSA was bound to a similar extent in the transformed and parental cell lines. One clone of polyoma-transformed 3T3, PY-3T3-4A (ref. 13), has consistently shown low levels of MSA binding (10–20% of the control 3T3 cells), but three other independently isolated polyoma-transformed 3T3 clones showed normal levels of MSA binding. Transformation of cells in culture, then, is apparently not associated with a specific alteration of MSA receptors.

In striking contrast is the selective loss of MSA binding to two cell lines that have been established from human fibrosarcomas (Figs 3c,d). These lines, 8387 (ref. 14) and HT1080 (ref. 15) have been previously characterised. Line 8387 was derived from a 25-yr-old female with fibrosarcoma of the leg; HT1080 was from a 35-yr-old male with a fibrosarcoma of the acetabulum. Less than 5% as much ^{125}I -MSA was bound by the 8387 and HT1080 fibrosarcoma cell lines than by foetal and newborn fibroblasts. In contrast, ^{125}I -EGF bound to comparable extents and with the same kinetics to the same fibrosarcoma cells and to embryonic and newborn human fibroblasts. The low binding of ^{125}I -MSA to the fibrosarcoma cells did not result from an altered kinetics of binding (Figs 3c, d). Neither did it seem to result from degradation of ^{125}I -MSA by the fibrosarcoma cells. Pre-incubation of ^{125}I -MSA with 8387 cells for 2 h

Fig. 2 Competition for ^{125}I -MSA binding by unlabelled peptides. ^{125}I -MSA (0.2 ng ml^{-1} ; $14,000 \text{ c.p.m.}$) was incubated with NRK clone 2 cells (9.5×10^5) for 90 min at 22°C in the presence of varying amounts of unlabelled peptides. MSA, $\bullet$; EGF, Δ ; nerve growth factor, $\blacktriangle$ (gift from R. Levi-Montalcini); fibroblast growth factor, $\blacklozenge$ (gift from D. Gospodarowicz); crystalline zinc porcine insulin, $\diamond$ (Lilly). Nonspecific binding (the ^{125}I -bound ligand which could not be competed by a large excess of unlabelled ligand) has been subtracted. The data presented are the mean of duplicate determinations. The % of control binding (2.1% of input radioactivity) is plotted against the log of the unlabelled competing peptide.

Fig. 3 Time course of association of ^{125}I -EGF (a, c) and ^{125}I -MSA (b, d) to different cell types. a, b: ^{125}I -EGF (a) or ^{125}I -MSA (b) were incubated with normal mink cells ($\bullet$, 7×10^5 cells per dish) or Kirsten sarcoma virus transformed mink cells ($\circ$, 6×10^5 cells per dish). c, d: ^{125}I -EGF (c) or ^{125}I -MSA (d) were incubated with four human lines or strains: 8387, a human fibrosarcoma line ($\bullet$, 7×10^5 cells per dish); HT1080, another human fibrosarcoma line ($\circ$, 5×10^5 cells per dish); HuF, a human foreskin fibroblast strain ($\square$, 4×10^5 cells per dish); WI38, a human embryonic lung fibroblast strain ($\blacksquare$, 4×10^5 cells per dish). The data are not corrected for counter background ($\sim 60 \text{ c.p.m.}$) nor nonspecific binding ($\sim 250 \text{ c.p.m.}$ for ^{125}I -MSA).

did not destroy the ability of the ligand recovered from the incubation medium to bind to receptor-positive cells. Similarly, fibrosarcoma cells cocultivated at fiftyfold excess (2×10^6 cells per plate) with NRK clone 2 cells (4×10^4 cells per plate) did not inhibit ^{125}I -MSA binding to the rat cells.

The lack of MSA binding to the two human fibrosarcoma cell lines is especially distinctive because MSA binds well to fibroblasts and other mesenchymal cells from humans and other species, and to cell lines established from a variety of other human tumours. MSA receptors were found in 34 out of 34 fibroblast strains from 12 different species. More than 20 normal human fibroblast strains derived from foetuses, newborns, and adults of various ages showed more than 10 times greater MSA binding than that of the fibrosarcoma lines. Further, loss of MSA receptors is not a general property of human tumour cells in culture, since other human tumour lines including chondrosarcomas, glioblastomas, and renal cell carcinomas specifically bound labelled MSA (in preparation).

Since the progenitor cells of the fibrosarcomas presumably had MSA receptors, the selective loss or unavailability of MSA receptors in the fibrosarcoma cell lines suggests the possibility that an alteration in the MSA-

receptor system may have had a role in the cellular transformation process. It is intriguing that fibrosarcomas are among the human tumour types that have been associated with clinical hypoglycaemia not attributable to elevated plasma insulin levels¹⁶. Markedly elevated levels of NSILA-s, a polypeptide with weak insulin-like activity, were identified in the serum of one patient with a fibrosarcoma and hypoglycaemia; presumably the tumour was the source of the circulating NSILA-s¹⁷. NSILA-s and MSA are closely related peptides that interact with the same receptors^{4,7,10,11}. This raises the possibility that the fibrosarcoma cell lines produce MSA-like polypeptides. The endogenous peptide production might occupy receptors, or regulate their availability¹⁸. Experiments to test for production of these factors by the fibrosarcoma lines in culture are in progress.

Thus, the binding of two polypeptide growth factors, EGF and MSA, seems to be selectively altered in different types of cell transformation. MSA binding is markedly reduced in two human fibrosarcoma cell lines, whereas EGF binding is abolished by murine and feline sarcoma virus transformation. While the precise relationship between the availability of growth factor receptors and transformation is unknown, we propose the following model for consideration. Cell growth in an organism is controlled, in part, by the particular display of specific growth factor receptors responding to hormones produced by other cells. In the normal situation, those cells that produce a specific growth factor do not also respond to it. But, the inappropriate production by a target cell of an active hormone that it also has receptors for may be sufficient to serve as a stimulus to cell division. Persistent uncontrolled production of the growth factor may then serve as a continuous endogenous stimulus and lead to inappropriate cell growth.

We thank Charlotte Meyer and Mary Ann McDonald for excellent technical assistance. This work was supported in part by the Virus Cancer Program of the US NCI.

Simian virus 40 facilitates multiplication of replication defective mutants of polyoma virus in BALB/3T3 mouse cells

STUDIES on conditionally lethal mutants of polyoma virus or simian virus 40 (SV40) should provide information on viral gene functions in infected cells. Temperature-sensitive mutants of polyoma virus^{1–4} and SV40 (refs 5–8) and a host range mutant of polyoma virus^{9,10} have already been isolated. But, the functional relationship between the viral genes of polyoma virus and SV40 has not yet been studied. To examine the relationship between the viral gene functions of polyoma virus and SV40, and changes of the cellular regulation system in cells transformed by SV40, we attempted to isolate new host range mutants of polyoma virus which could replicate in mouse cells transformed by SV40 but not in normal mouse cells. We report here the isolation of two host range mutants of this type. Productive infection of these mutants in A31-714 cells¹¹ (subclone of mouse BALB/3T3), which are restrictive for these mutants, is facilitated by co-infection with SV40.

Host range mutants were isolated from ultraviolet-irradiated polyoma virus (strain: LP147-2). A sample of 2 ml of fluid containing polyoma virus was put into a Petri dish (40 mm in diameter) and irradiated for 3 min under a Toshiba germicidal lamp (15 W×2) from a distance of 15 cm with gentle shaking. In these conditions, the plaque-forming ability of the polyoma virus was reduced to 10⁻³ of the initial value. After irradiation, appropriate dilutions of the sample were plated on subconfluent monolayers of SA31 cells (A31-714 cells transformed by SV40 with the following properties; (1) SV40 T-antigen positive, (2) virus-free, (3) SV40 inducible by cell fusion with CV-1 cells by UV-HVJ, and (4) capable of use in plaque assay of polyoma virus). After 7–8 d single plaques were picked up and each was tested for its ability to produce plaques on confluent monolayers of A31 cells.

Two of 576 plaques tested failed to produce distinct plaques on A31 cells. The mutants obtained by three further sequential plaque purifications on SA31 were named HR-86 and HR-101.

Table 1 shows the abilities of mutant HR-101 to form plaques on monolayers of A31-714 cells and SA31 cells. The plaque forming ability of the wild type was the same on both indicator cells, whereas that of HR-101 was 10⁻²

Table 1 Plaque-forming abilities of HR-101 in A31-714 cells and SA31 cells

Type of virus	Type of cells	PFU per ml
HR-101	A31-714	< 10 ⁴
HR-101	SA31	3.1 × 10 ⁶
WT	A31-714	2.1 × 10 ⁶
WT	SA31	2.0 × 10 ⁶

Plaques were counted 8 d after virus infection. PFU, plaque-forming units.

or less on A31-714 cells than on SA31 cells. Cytopathogenic effects were seen, however, when low dilutions of HR-101 samples were inoculated on to monolayers of A31-714 cells.

To see whether the reduction in the plaque-forming ability of HR-101 in A31-714 cells was due to decrease in virus yield, the replications of the mutant in A31-714 cells and in SA31 cells were compared.

A31-714 cells and SA31 cells were both infected with HR-101 and 6 h later uninfected virus was washed out and production of virus was followed at 24-h intervals.

When HR-101 was inoculated on to A31-714 cells, it did not show appreciable multiplication, but when it was inoculated on to SA31 cells it multiplied: multiplication

Fig. 1 Cultures of A31-714 and SA31 inoculated with HR-101, Wt, HR-101 plus SV40 (777 strain) or WT plus SV40. The multiplicities of infection of HR-101 and WT were 0.03 and that of SV40 was 60. After adsorption at 37 °C for 6 h, cultures were washed three times with medium, covered with 5 ml of Eagle's MEM medium containing 10% calf serum and incubated at 37 °C at 24 h intervals, cultures were collected and stored frozen. Cells and media were sonicated and their virus titres were assayed by plaque formation on cultures of SA31 cells. Growth of HR-101 (a) and WT (b) in SA31 cells (○), in A31-714 cells without SV40 (△) and in A31-714 cells with SV40 (●).

was detectable after 2 d and reached a maximum after 3–4 d (Fig. 1a). In contrast, the wild type multiplied equally well in A31-714 cells and SA31 cells (Fig. 1b).

To determine whether the change in susceptibility of A31-714 cells to infection by the mutant was caused by SV40, the helper function of SV40 in multiplication of the mutant in A31-714 cells was also examined. A31-714 cells were co-infected with HR-101 (multiplicity of infection (m.o.i.), 0.03) and SV40 (m.o.i., 60) and the yields of HR-101 were followed by the method described above.

The yield of HR-101 in A31 cells was enhanced approximately 60-fold by co-infection with SV40 (Fig. 1a).

When SV40 samples were treated with anti-SV40 rabbit serum, their ability to enhance the replication of HR-101 disappeared completely (Table 2). The viral characters of HR-86 were similar to those of HR-101 described above.

In preliminary experiments, cells in primary cultures from embryos of a BALB/c mouse also showed low susceptibility to host range mutants and co-infected SV40 enhanced the growth of these mutants in the primary cells (data not shown).

These results suggest that SV40 converts the susceptibility of mouse cells to infection with these mutants from a restrictive to a non-restrictive state. Although the role of SV40 in this conversion of cellular susceptibility has not yet been elucidated, the restrictive point to the infection of HR-101 in A31-714 cells may be considered not before the penetrat-

Table 2 Effect of anti-SV40 serum on the helper function of SV40

Type of infection	Type of cells	Virus titre per ml*	Enhancement ratio
HR-101	A31-714	7.8×10^3	1.0
HR-101+SV40	A31-714	4.5×10^4	57.7
HR-101+(SV40)†	A31-714	2.8×10^3	0.4
HR-101	SA31	1.0×10^5	128.2

Cultures of A31-714 and SA31 containing 3.2×10^5 cells per 4-cm plastic dish were inoculated with HR-101 at a multiplicity of 0.03. Some cultures of A31-714 were inoculated with both HR-101 and SV40 (m.o.i., 10) or HR-101 and SV40 which had been treated with anti-SV40 serum. After adsorption at 37 °C for 6 h, cultures were washed three times with medium and covered with 5 ml of Eagle's MEM medium containing 10% calf serum. These cultures were collected 72 h later. The cells and media were sonicated and virus infectivity in the lysates was assayed by plaque formation on cultures of SA31 cells.

*72 h post-infection.

†Treated with anti-SV40 serum.

ing step but after the uncoating step, because DNA from HR-101 was also considerably less infectious to A31-714 cells than to SA31 cells (Table 3). The defect in virus growth of the mutants may be helped either by the direct action of a SV40 viral gene product(s) present in both SV40-transformed cells and mouse cells abortively infected with SV40, or by the indirect action in which a SV40 genome in these cells alters the expression of cellular genes. In any case, an 'early' event(s) of SV40 infection may be concerned with change in susceptibility to these host range mutants because SV40 did not produce 'late' gene products in mouse cells on either infection or transformation^{12,13}.

Table 3 Virus yields after infection with viral DNA

DNA	DNase treatment (20 µg ml ⁻¹)	Yield (PFU per culture) A31	Yield (PFU per culture) SA31	Ratio SA31 : A31
Wt	—	1.5×10^3	1.8×10^3	1.2
	+	< 10	< 10	—
HR-101	—	5.0×10^4	9.0×10^3	180.0
	+	< 10	< 10	—

A confluent monolayer of A31-714 cells or SA31 cells in a 6-cm Petri dish was washed once with 5 ml of phosphate-buffered saline and then infected with 0.1 ml of a mixture containing wild-type DNA (7.2×10^3 PFU: assayed on SA31 cells) or HR-DNA (2.8×10^3 PFU: assayed on SA31 cells), DEAE-dextran (500 µg ml⁻¹) and Tris-HCl (pH 7.5, 0.05 M). After incubation at room temperature for 30 min, the cells were washed once and then 5 ml of growth medium (MEM + 10% calf serum) were added. After 3 d at 37 °C, cells and fluids were collected, sonicated and assayed on SA31 cells to determine virus yield.

Further experiments on the characteristics of host range mutants and on the relation between the gene functions of polyoma virus and SV40 are in progress.

I thank Dr K. Toyoshima for discussions and Mrs Y. Fukushima for assistance. This work was supported by the Ministry of Education, Science and Culture, Japan.

Extraneural localisation of herpes simplex virus in latently infected guinea pigs

CHRONIC latent herpes simplex virus (HSV) infections are associated with tissues of the nervous system in experimentally infected mice and rabbits^{1,2} as well as in humans^{3–5}. Cook and Stevens demonstrated, that, after inoculation into the skin, HSV migrates via the subserving nerves to the corresponding sensory ganglia⁶. The virus establishes there a latent infection which can be detected by methods of *in vitro* cultivation of the ganglia^{1–3}. A consideration of the data obtained so far on the behaviour of latent HSV in mice, rabbits and men led Cook and Stevens as well as Baringer to the postulate, that latent HSV infections were restricted to tissues of the nervous system^{7,8}. The failures to detect HSV in the skin during latent infections are con-

sistent with this hypothesis^{9,10}. Recurrent HSV infections are thought to arise by activation of the latent infection within the ganglia and the subsequent migration of the reactivated virus into the skin via the corresponding nerve fibres^{8,11}. I have described recently experimental infections of guinea pigs with HSV type 2, which led to chronic latent infections of the animals with frequent spontaneously recurring lesions at the sites of initial inoculation^{12,13}. In this report I present evidence that during the latent phase of the infection HSV can be recovered not only from nervous tissues but also from the skin at the site of the primary infection.

Fifteen albino guinea pigs were inoculated with 10⁴ plaque-forming units of HSV type 2, strain 72, subcutaneously into the left hind footpad. They were observed for clinical signs of primary and recurrent herpetic lesions three times a week. The animals were sacrificed between 3 and 7 months after infection at times when they did not show any clinical sign of recurrent infection. Pertinent tissues were taken from exsanguinated animals and assayed for latent virus by explantation on monolayers of primary rabbit kidney (PRK) cells as described previously¹¹. All isolates were passaged once on PRK cells and identified as HSV by neutralisation with an anti-HSV hyperimmune serum, prepared in rabbits.

The data (Table 1) show, that all 15 animals harboured latent HSV, irrespective of whether they had developed previous recurrent infections or not. Surprisingly, however, from 14 of the animals virus was isolated from the skin of the initially infected footpad, whereas only eight animals were shown to harbour virus in their lumbosacral dorsal root ganglia and three animals in the lumbosacral part of the spinal cord. In addition, HSV was recovered from the sciatic nerve trunks of seven animals.

To test whether chronic latent infections of guinea pigs could be established with HSV type 1 as well and if so, where the virus would be located, a group of animals was similarly infected with HSV type 1, strain McIntyre. This strain does not induce recurrent infections in guinea pigs (unpublished). Chronic latent infection of the skin of the footpad was detected in six out of eight animals (Table 2).

None of the eight guinea pigs, however, could be shown to harbour latent virus in their nervous system.

The surprising finding that HSV could be recovered preferentially from the skin of the footpad during the clinically quiescent phase of the infection offers two alternative interpretations. First, in contrast to the well documented restriction of latent HSV infections to tissues of the nervous system in mice and rabbits, guinea pigs may harbour latent HSV type 2 preferentially and latent HSV type 1 exclusively in the skin at the site of the primary inoculation. Alternatively, HSV infections of guinea pigs may be no exceptions to the rule that latent virus resides exclusively in nervous tissues. Such latent virus may, however, become frequently or even consistently reactivated in the ganglia to spread via peripheral nerves into the skin, although overt clinical disease may be only rarely induced. The latently infected ganglia may harbour only small amounts of virus, frequently escaping detection in our assay, whereas the skin, and in some animals also the nerve trunks, may contain enough reactivated virus to be more easily recovered.

The second explanation seems more likely as it is essentially consistent with data, obtained in other species. In addition, it could support a hypothesis on the pathogenesis of recurrent herpes infections, suggested recently by Hill and Blyth¹⁴. According to this theory, virus is frequently activated in ganglia, travels to the skin, and induces micro-foci of infected epidermal cells, which are usually eliminated by the host's defence mechanisms. Visible lesions develop only under some additional alteration of the local environment. If this theory is correct, virus should be frequently detectable in the skin. The previous failures to recover virus from skin of mice and men^{9,10} using organ culture may be due to the comparatively rare spontaneous reactivation of the latent virus within the ganglia in these species.

Further experiments in neurectomised guinea pigs should help to determine which of these alternative interpretations is correct. Evidence was given in a previous report¹², that HSV travels along the sciatic nerve from skin to ganglia and vice versa. Dissection of the nerve before infections should therefore prevent the establishment of latent infection in ganglia. Consequently, in such animals neither

Table 2 Recovery of virus from animals infected with HSV type 1

313	4/4	0/4	0/4		0/4

recurrent lesions nor latent virus in the skin of the footpad should be found, if the second explanation holds. Such experiments are currently under way.

Relationship between cell shape and type of collagen synthesised as chondrocytes lose their cartilage phenotype in culture

WHEN chondrocytes from sternal or articular cartilage are kept in monolayer culture at low density, they eventually lose their cartilage phenotype^{1–4}. Within four passages or approximately 1 month in culture they change from a polygonal or round to a flattened, amoeboid-like shape^{5–7}, and instead of cartilage collagen (type II collagen⁸) they synthesise the genetically different type I collagen. It is not known whether there is a strict correlation between the occurrence of cell flattening and the change in collagen synthesis within individual cells. We have reported that preferentially flattened, fibroblast-like cells at the edge of cartilage colonies synthesise type I collagen, whereas round or polygonal chondrocytes generally synthesise type II collagen^{1–3}. The change is nearly complete in a culture at a time when excessive flattening is observed⁴. Using an immunofluorescence double staining technique^{9,10}, we have now found that there is no strict correlation between cell morphology and type of collagen synthesised.

We used chondrocytes from 16-day embryonic chick sternal cartilage, which were released by treatment with trypsin and collagenase^{1–3} and cultured on tissue culture plastic dishes at a density of 10^4 cells per cm^2 in Ham's F12 medium and 10% foetal calf serum. In these conditions the change from type II to type I collagen synthesis was nearly complete within 1 month.

The type of collagen synthesised by individual cells was determined at various stages of dedifferentiation by immunofluorescence using specific antibodies to type I and type II collagen⁹. This facilitated the comparison of cell shape and the type of collagen synthesised. The double staining procedure enabled us to determine whether a single cell could synthesise both types of collagen simultaneously¹⁰. During the first day of culture the chondrocytes remained almost round; staining with rabbit anti-type II collagen antibodies revealed strong fluorescence of the cell membrane and of numerous filopodia (Fig. 1a). Because of strong membrane-bound fluorescence no intracellular type II collagen or procollagen could be detected. No positive reaction with antibodies to type I collagen was obtained at this stage. After 2 d most chondrocytes had settled on the surface, flattened and retracted their filopodia. These cells showed little membrane bound fluorescence, for the nucleus appeared dark after staining with anti-type II collagen antibodies, but strong intracellular fluorescence (Fig. 1b). This was probably due to type II procollagen, the intracellular form of collagen¹¹, which seemed to be packed in

Fig. 1 Immunofluorescent staining of chondrocytes from 16-day embryonic chick sterna with antibodies against type II collagen after 24 h in culture. Chondrocytes were released from sterna by treatment with 0.25% trypsin and 0.1% crude collagenase for 90 min at 37 °C, washed with F12 medium plus 10% foetal calf serum, and plated on Falcon plastic dishes No. 3001 at cell densities of 10^4 cells per cm^2 in Ham's F12 medium and 10% foetal calf serum^{1–3}. After 24 h most cells had attached to the surface, but none were flattened; they showed strong membrane-bound fluorescence and numerous filopodia. For immunofluorescent staining, cells were washed with saline and fixed with 70% ethanol followed by 98% ethanol-ether (1:1, v/v). The air dried cells were reacted with monospecific rabbit antibodies to chick type II collagen (0.12 mg ml^{-1}) for 30 min at room temperature, washed and counterstained with fluorescein conjugated goat anti-rabbit γ globulin as described earlier⁹. Preparation and specificity of the antibodies was described previously⁹. Cells did not stain with antibodies to type I collagen at this time in culture. $\times 260$. **b**, Immunofluorescent staining (see Fig. 1) of a chondrocyte colony after 48 hours in culture. Cells have flattened and retracted their filopodia. Fluorescence with antibodies to type II collagen is located mostly intracellularly as indicated by the weak staining of the membrane above the nuclear area. $\times 260$.

large vacuoles in some cells (Fig. 2). These vacuoles appeared dark in the phase contrast microscope after fixation and antibody staining (Fig. 2b) but were not visible in living cells. It cannot be ruled out that they were an artefact of the fixation and drying procedure, but we assume that they are secretory granules filled with procollagen¹².

After 2 d in culture the first cells started to produce type I collagen. Biochemical determinations have shown that after 2 weeks about 50% of the newly synthesised collagen was type I collagen^{1–3}. Double staining with antibodies to type I and type II collagen revealed that most cells synthesised either type I or type II collagen (Fig. 3). Only in about 1 out 100 cells was fluorescence observed with both antibodies. There was no significant difference in the morphologic appearance of type I and type II collagen synthesising cells. We observed cells of nearly identical shape in close proximity, which may have originated from the same mother cell, one synthesising type I and the other type II collagen (Fig. 3, arrows).

Type I as well as type II collagen synthesising binucleated cells were observed in increasing amount with prolonged

Fig. 2 Immunofluorescence (a) and phase contrast micrograph (b) of the same cells of a 12-day chondrocyte culture after fixation and staining with antibodies to type II collagen. Fluorescence seems to focus in large intracellular vacuoles (arrows) which may be secretory granules containing type II procollagen. The phase contrast is low because the cells were fixed and air dried. This kind of vacuole was not seen in phase contrast microscopy of living cells. ($\times 478.5$).

Fig. 3 Immunofluorescent double staining of a chondrocyte culture after 14 d in culture with rabbit antibodies to type I collagen followed by rhodamin conjugated goat anti-rabbit γ -globulin, and guinea pig antibodies to type II collagen followed by fluorescein conjugated rabbit anti-guinea pig γ -globulin⁹. In (a) the fixed culture was photographed with a red filter Rfl 580 (Zeiss), revealing only type I collagen-bound rhodamine fluorescence, and (b) shows type II collagen-bound fluoresceine reaction of the same cell group, photographed through a KP490 filter (Zeiss)⁹. Most cells synthesise either type I (I) or type II (II) collagen except for the cell labelled by an asterisk (*) which shows fluorescence with both types of antibodies. Type I and type II collagen synthesising cells are often located in close proximity and of nearly identical cell shape (arrows). Binucleated cells (B) may produce type I or type II collagen. $\times 360$.

time in culture (B in Fig. 3), which may have been created by incomplete mitosis or cell fusion.

This experiment demonstrates, first, that no conclusions can be drawn from the morphological appearance of a cultured chondrocyte about the type of collagen the cell is producing. Second, because only a few cells were observed which synthesised type I and type II collagen simultaneously, it is evident that the cells do not change gradually from type II to type I collagen synthesis, but rather abruptly. Since the overall transition from type II to type I collagen synthesis in a culture is a gradual process extending through several weeks¹⁻⁴, individual cells must 'switch' at different times in culture. This is consistent with the observation of an increasing number of type I collagen producing cells during the cell culture period, associated with a decreasing number of type II collagen producing cells.

The reason for individual differences in the stability of the chondrocyte phenotype within the cell population obtained after dissociation of embryonic sterna is still unclear. It is possible that young chondroblasts derived from regions underneath the perichondrium had to undergo more doublings to dedifferentiate than did older chondrocytes from the centre of the sternum which were closer to hypertrophy than subperichondral cells. We have also

observed that in general cells located at the periphery of cartilage making colonies³ or cells in between those had changed to type I collagen synthesis earlier than cells from the centre of the colony. This indicates that the stability of the chondrocyte phenotype is also dependent on cell-cell or cell-matrix interactions.

Effect of prostaglandin endoperoxides and metabolites on bone resorption *in vitro*

PROSTAGLANDINS are potent bone resorbers¹ which have been implicated as mediators of bone loss and hypercalcaemia in disease²⁻⁶, but the specific products in the pathway of prostaglandin synthesis and degradation which are responsible have not yet been identified *in vivo*. Although PGE₂ is the most potent stimulator of bone resorption among the prostaglandins thus far tested *in vitro*⁷, in animal tumour models, the increase in immunoreactive PGE₂ concentrations does not correlate well with the development of hypercalcaemia². We therefore tested the early products of arachidonic acid metabolism via the cyclo-oxygenase pathway, the prostaglandin endoperoxides (PGG₂ and PGH₂) and some of the 13,14-dihydro (H-PGE₂ and H₂-PGE₁) and 15-keto-13,14-dihydro metabolites of prostaglandins (15K-H₂-PGE₂ and 15K-H-PGF_{2α}) for their effects on the release of previously incorporated ⁴⁵Ca from cultured foetal rat long bones. The endoperoxides were found to cause a rapid transient increase in the release of previously incorporated ⁴⁵Ca from bone, but did not stimulate prolonged resorption. H₂-PGE₂ and H₂-PGE₁ were almost as potent as the parent compounds. 15K-H₂-PGE₂ and 15K-H-PGF_{2α} were much less potent, but did stimulate resorption at 10⁻⁶ M.

The diseases in which increased prostaglandin production has been implicated as the mediator of pathologic bone loss include malignancy^{2,3}, rheumatoid arthritis⁴, and periodontal disease^{5,6}. Bone itself can produce prostaglandin when cultured with antibodies to cell surface components and complement⁸. Moreover, PGE₂ can inhibit bone collagen synthesis as well as stimulate bone resorption⁹.

There is clear evidence for an increased metabolism of arachidonic acid via the cyclo-oxygenase pathway in the hypercalcaemia of malignancy, as markedly increased levels of PGE₂ metabolites have been found in the blood of hypercalcaemic mice with the HSDM₁ fibrosarcoma¹⁰ and hypercalcaemic rabbits bearing the VX₂ tumour¹¹ and in the urine of patients with the hypercalcaemia of cancer². It has been more difficult, however, to prove that PGE₂ itself is the circulating material responsible for hypercalcaemia. In animal tumour models a modest increase in immunoreactive PGE₂ is seen only after hypercalcaemia has developed², and in patients

with the hypercalcaemia of cancer the evidence for increased circulating immunoreactive PGE_2 is conflicting^{12,13}. Low levels of circulating PGE_2 in the presence of its increased synthesis are most likely the result of its rapid metabolism by the lung and other tissues so that PGE_2 itself may not accumulate in the circulation¹⁴. This raises the possibility that either metabolites of PGE_2 or other products of arachidonate metabolism via the cyclo-oxygenase pathway such as thromboxane or prostacyclin¹⁵ might stimulate osteoclastic activity and produce hypercalcaemia.

Accordingly, we have evaluated the bone resorption produced by PGG_2 and PGH_2 , the labile cyclic endoperoxides from which all prostaglandins and thromboxanes are formed¹⁶. We have also examined the major metabolite of PGE_2 that persists in the circulation, 15-keto-13,14-dihydro- PGE_2 ($15\text{K-H}_2\text{-PGE}_2$), the major product of metabolism by the lung, as well as 13,14-dihydro- PGE_2 ($\text{H}_2\text{-PGE}_2$) which is produced by reduction of the 15-keto group of $15\text{K-H}_2\text{-PGE}_2$ in organs such as the liver¹⁷. Finally, we compared some analogous compounds, PGE_1 , $\text{H}_2\text{-PGE}_1$ and $15\text{K-H}_2\text{-PGF}_{2\alpha}$.

The endoperoxides, PGG_2 and PGH_2 , were prepared according to the method of Hamberg *et al.*¹⁸; following isolation by silicic acid chromatography their purity and structures were confirmed by thin layer chromatography and mass spectrometry of their respective reduction and isomerisation products¹⁹. $\text{H}_2\text{-PGE}_2$, $\text{H}_2\text{-PGE}_1$, $15\text{K-H}_2\text{-PGE}_2$ and $15\text{K-H}_2\text{-PGF}_{2\alpha}$ were prepared by incubation of ^3H -labelled and unlabelled precursors with homogenates of guinea pig liver by the method of Hamberg and Israelsson¹⁷. The products were resolved initially by reversed phase partition chromatography with solvent system C-50 (ref. 20) and further purified with high performance liquid chromatography²¹. The structures were confirmed by mass spectrometry. PGE_2 and its metabolites were quantified on the basis of radioactivity after standardisation by gas chromatography.

The effects of prostaglandin endoperoxide and metabolites on bone resorption were assessed by measuring the release of previously incorporated ^{45}Ca from foetal long bones cultured in a chemically defined medium with 4 mg ml⁻¹ bovine serum albumin as described previously^{7,22}. The bones were precultured for 18–24 h to remove exchangeable ^{45}Ca . The endoperoxides were stored at -80°C in acetone and were injected into the culture medium in 1 μl of acetone per 500 μl of medium. Controls received acetone alone. The metabolites were added in alcohol (less than 0.1% final concentration). Controls received alcohol alone. ^{45}Ca release was measured in medium and bone and the per cent of total bone ^{45}Ca released during each culture period calculated.

The prostaglandin endoperoxides, PGG_2 and PGH_2 , did not produce consistent stimulation of bone resorption in 48-h cultures when injected at 3–12 h intervals. Their effect was always less than that of equivalent amounts of PGE_2 administered in an identical manner. Because of their short half life, the effects of more frequent injections were examined. Bone cultures were injected hourly with endoperoxides or PGE_2 for 5 h and calcium release measured at 6 h. The cultures were then transferred to fresh medium to see if further resorptive responses occurred. Using this schedule, PGG_2 at 10^{-6} and 10^{-8} M and PGH_2 at 10^{-6} and 10^{-7} M increased the release of ^{45}Ca from foetal bones at 6 h (Table 1). The effect of PGH_2 at 10^{-8} M was tested in four additional experiments; in two of these ^{45}Ca release was increased significantly by 20–25%. Hence 10^{-8} M PGH_2 is apparently at or near the threshold concentration for early ^{45}Ca release. PGE_2 at 10^{-6} to 10^{-8} M did not produce a significant 6-h increase in ^{45}Ca release in any experiment. After 6 h of treatment with PGE_2 , however, there was always a significant resorptive response during the subsequent 42 h of culture. The 6–48-h response after endoperoxide treatment was quite variable and usually not statistically significant. A prolonged response to brief exposure has been observed with other stimulators of bone resorption²³ and has been termed induction. Because the rapid effects of

Values are means ± s.e. for four to twelve bone cultures treated with 5-hourly injections of prostaglandin in acetone beginning at 0 time; controls received acetone alone. Cultures were transferred to fresh medium without prostaglandins or acetone at 6 h.

*Significantly different from controls, $P < 0.01$.

endoperoxides were small in terms of total bone calcium, it was not possible to determine whether there was stimulation of matrix resorption as well as calcium release at 6 h. The initial effect could have been due to an increase in cell permeability to calcium²⁴. High calcium concentrations in the medium have previously been shown to inhibit induction by parathyroid hormone²⁰. It is possible that the calcium released by endoperoxides could decrease the subsequent resorptive response even if a substantial amount of PGE_2 were produced. It is also possible that the endoperoxides produced tissue damage which impaired resorptive response. We have, however, observed that endoperoxide-treated bone can respond to subsequent addition of both PGE_2 and parathyroid hormone (data not shown).

The metabolites of PGE_2 , PGE_1 and $\text{PGF}_{2\alpha}$ which may have a longer half life in the circulation than the parent compounds were tested only in prolonged continuous cultures. Both $\text{H}_2\text{-PGE}_2$ and $\text{H}_2\text{-PGE}_1$ were nearly as potent as the parent compounds (Fig. 1) and as previously reported⁸ PGE_1 was somewhat less potent than PGE_2 . In contrast, $15\text{K-H}_2\text{-PGE}_2$ and $15\text{K-H}_2\text{-PGF}_{2\alpha}$ were much less effective. Some stimulation of resorption was observed at 10^{-5} M (Table 2). In another experiment 89% of total ^{45}Ca released after 5 d treatment with $15\text{K-H}_2\text{-PGE}_2$ at 2×10^{-5} M, but at 2×10^{-4} M, the highest concentration tested, $15\text{K-H}_2\text{-PGE}_2$ actually inhibited ^{45}Ca

Fig. 1 Effect of prostaglandins E_2 (●) and E_1 (■) and their 13,14-dihydro metabolites, $\text{H}_2\text{-PGE}_2$ (○) and $\text{H}_2\text{-PGE}_1$ (□), on release of previously incorporated ^{45}Ca from cultured foetal rat long bones. Data from eight experiments were pooled and the points are means for 6–22 cultures incubated for 5 d with medium changed at 2 d. Standard errors were 5 to 15% of the means. The differences from control at 10^{-7} and 10^{-6} M were significant at $P < 0.01$, at 10^{-8} M at $P < 0.05$. Broken line represents control levels. a, Release at 2 d; b, release at 5 d.

Table 2 Effect of 15K-H₂-PGE₂ and 15K-H₂-PGF_{2α} on release of previously incorporated ⁴⁵Ca from cultured foetal rat long bones

Treatment	% of total bone ⁴⁵ Ca released
Control	40.3 ± 4.1
15K-H ₂ -PGE ₂ 10 ⁻⁷ M	43.8 ± 5.0
10 ⁻⁶ M	48.0 ± 6.4
10 ⁻⁵ M	54.1 ± 2.9*
15K-H ₂ -PGF _{2α} 10 ⁻⁷ M	38.0 ± 4.3
10 ⁻⁶ M	38.2 ± 3.7
10 ⁻⁵ M	55.5 ± 6.4*

Values are mean ± s.e.m. for four to eight bones cultured for 5 d. Medium was changed at 2 d.

release to 25% compared with a control of 41%. The inhibition may be a toxic effect and has been seen with other prostaglandins at high concentrations⁸. At their maximally effective doses, all the agents tested produced similar morphological changes with almost complete resorption of mineral and matrix at 5 d. To exclude any possible contribution of different binding to albumin to the relative potencies of these compounds, a separate experiment was performed in which medium without albumin was used, and PGE₂ stimulated bone resorption significantly at 10⁻⁸ M while 15K-H₂-PGE₂ was again ineffective at 10⁻⁶ M. These results indicate that the 13,14-dihydro derivatives are nearly as potent stimulators of bone resorption as PGE₂ and PGE₁, whereas 15K-H₂-PGE₂ is considerably less potent. Atkins and Martin²⁵ found a similar relation between metabolites and parent compounds for stimulation of cyclic AMP production by osteogenic sarcoma cells. It will be of interest to determine whether any of these compounds can accumulate sufficiently in the circulation to contribute to the resorption of bone in the hypercalcaemia of cancer.

The prostaglandin endoperoxides, PGG₂ and PGH₂, cause a transient stimulation of calcium release that is quite different from the prolonged resorption resulting from PGE₂. These findings raise the possibility that bone tissue enzymically converts PGG₂ and PGH₂ to a labile product such as thromboxane A₂ or prostacyclin (PGX). Further studies will be required to delineate which of the products of arachidonate metabolism via the cyclooxygenase pathway account for the resorption of bone in neoplasia and inflammation.

Increased cyclic GMP levels associated with contraction in muscle fibres of the giant barnacle

CYCLIC GMP has been implicated as an intracellular second messenger in a variety of systems. In particular, a number of hormones and neurotransmitters have been shown to raise cellular cyclic GMP levels *in vitro*^{1–9}. In many of these systems, however, Ca²⁺ entry seems to be responsible both for the physiological effect of the hormone and for the hormone-stimulated increase in cyclic GMP (refs 4–9). We have investigated the relationship between calcium and cyclic GMP levels in muscles of the giant barnacle *Balanus nubilus*. This preparation has a number of advantages. Within fairly narrow limits intracellular free calcium levels in the resting muscle are known¹⁰. The depolarisation-induced increase in free calcium, and the resulting activation of contraction, have also been extensively documented^{10,11}. In addition, the depolarisation-induced changes in intracellular free calcium can be easily manipulated because the extracellular fluid is the apparent source of the calcium which couples excitation to contraction¹². We report here that either KCl depolarisation or nerve stimulation increases the cyclic GMP content of barnacle muscle. This increase seems to be associated with Ca²⁺ entry rather than with a neurotransmitter–receptor interaction *per se*. This is the first report of an increase in cyclic GMP associated with contractile activity in cross-striated muscle.

The three pairs of depressor muscles were used in all the experiments described below. The dissection of these muscles and their nervous supply has been described previously¹³. The cyclic GMP content of resting barnacle muscle, measured according to the procedure described in Fig. 1, was 75 ± 8 fmol per mg protein (mean ± s.e.m. for 34 individual resting muscles from a total of 18 barnacles).

Depolarisation of the muscles by elevating the KCl concentration of the barnacle saline for 2 min produced an increase both in isometric tension and in cellular cyclic GMP (Fig. 1). The isometric tension increased rapidly and reached a near-maximal value within 15 s. The cyclic GMP content was measurably elevated within 30 s and continued to increase until 2 min, at which time it was nearly three times control. Beyond this time, the cyclic GMP level fell towards that of resting muscle, even when the exposure to KCl was maintained. The cyclic GMP content declined toward the basal level despite the fact that the muscle was able to maintain a constant isometric tension for as long as the KCl stimulus was present (longest time tested = 5 min, data not shown). These results indicate that the cyclic GMP level does not directly control the contractile state. (Although we have not established the reason for the decline in cyclic GMP, it may be physiologically important; for instance, Ca²⁺ entry or some other event associated with muscle contraction might cause a rapid increase in the synthesis, and a slower increase in the degradation, of the nucleotide.) If, after 2 min of KCl depolarisation, the muscles were returned to normal barnacle saline, isometric tension decreased to the pre-stimulus level and the fall in cyclic

Fig. 1 Effect of KCl depolarisation on isometric tension (a) and cyclic GMP content (b) of giant barnacle muscle. The tension trace shows the effect of a 2-min exposure of the muscle to 100 mM KCl-barnacle saline followed by a return to control barnacle saline. The control barnacle saline (modified from ref. 13) had composition (mM): Na^+ , 476; K^+ , 8; Ca^{2+} , 20; Mg^{2+} , 12; Cl^- , 548; MOPS (3-(*N*-morpholino)propanesulphonic acid), 10; pH adjusted to 7.4 with NaOH. The 100 mM KCl-barnacle saline was made by equimolar substitution of K^+ for Na^+ in the control saline. The cyclic GMP data were calculated as follows: from each barnacle 1–5 muscles were used as test muscles and 1–3 muscles as control muscles. The cyclic GMP content of an individual test muscle was expressed as $100 \times (\text{pmol cyclic GMP per mg protein of the test muscle} \div \text{mean pmol cyclic GMP per mg protein of control muscle from the same barnacle})$. Thus, each barnacle yielded 1–5 experimental values. ○, Mean percentage ($\pm$ s.e.m.) cyclic GMP content, relative to control as described, for test muscles incubated for the indicated duration in 100 mM KCl-barnacle saline; ●, mean percentage cyclic GMP content, relative to control, of muscles returned to normal barnacle saline after 2 min in 100 mM KCl-barnacle saline. In all cases, control muscles were incubated in normal barnacle saline for a time equivalent in duration to the incubation of experimental muscles. All muscles were dissected and pre-incubated (1–3 h at 4 °C) in control barnacle saline. Experiments were carried out at room temperature (19–21 °C). After experimental incubations, cyclic nucleotides were extracted by rapidly homogenising the muscles with an Ultraturrax in 7–10 ml ice-cold 7% TCA. Alternatively, the muscles were first frozen in liquid nitrogen and then homogenised in TCA. The cyclic GMP level of resting muscle did not depend on which of these two treatments was used. The TCA-precipitated proteins were pelleted by centrifugation; after removing the supernatant the protein content of the pellets was measured by the method of Lowry *et al.*²². Aliquots (3 ml) of the supernatant were extracted five times with 10 ml water-saturated ether, lyophilised and reconstituted with 0.5 ml 50 mM sodium acetate, pH 6.2. Cyclic GMP was determined by the method of Steiner *et al.*²³ and cyclic AMP by the method of Brown *et al.*²⁴. The recovery of exogenous cyclic GMP and cyclic AMP, added to whole muscle homogenates, was 85% and 90%, respectively. Treatment of the sodium acetate-reconstituted samples with beef heart phosphodiesterase (Boehringer) reduced their cyclic nucleotide content essentially to zero.

GMP seemed to be slightly more rapid than in the continued presence of high KCl although the difference was probably not statistically significant (Fig. 1).

KCl depolarisation seemed to have relatively little effect on the cyclic AMP content of barnacle muscle, but these data are less complete. The basal cyclic AMP level was 3.57 ± 0.41 pmol per mg protein (mean $\pm$ s.e.m.; 12 muscles from 7 barnacles). Depolarisations ranging from 30 s to 2 min caused an increase of $19 \pm 6\%$ above control (14 muscles from 7 barnacles).

The effect of nerve-evoked contraction on the intracellular level of cyclic GMP is shown in Fig. 2. Repetitive nerve stimulation caused a maintained increase in tension, and a time-dependent increase in muscle cyclic GMP, during the interval studied.

To determine whether, as in many other systems⁴⁻⁹, the stimulated increases in barnacle muscle cyclic GMP level are

dependent on extracellular Ca^{2+} , muscles were soaked for 2–3 h in Ca^{2+} -free barnacle saline. After such treatment, depolarisation with Ca^{2+} -free 100 mM KCl-barnacle saline caused no visible contraction and no increase in cyclic GMP (Table 1, B1). The absence of an increase in cyclic GMP was not a result of deterioration of the muscle. Exposing muscles which had been preincubated in Ca^{2+} -free barnacle saline to Ca^{2+} -containing 100 mM KCl-barnacle saline caused a strong contraction and an increase in cyclic GMP comparable to that for muscles which had been preincubated in normal barnacle saline (compare B2 with A2 in Table 1).

Based on studies of other crustaceans¹⁴, glutamate is probably the excitatory neuromuscular transmitter in the barnacle. As support for this contention we found that bath applied glutamate (0.1–1.0 mM) caused barnacle muscle to contract; but this contraction was weak and variable, with a duration of usually less than 10 s. In such conditions (0.5 mM glutamate for 2 min), there was no alteration in muscle cyclic GMP ($101 \pm 18\%$, relative to control, for six muscles). The bath application of higher (10 mM) concentrations of glutamate caused a vigorous, brief (<1 s) contraction. The brevity of this contraction is probably a consequence of the rapid desensitisation of the muscle glutamate receptors. This desensitisation to applied glutamate was accompanied by a rapid reduction in the visible contraction induced by nerve stimulation, further supporting the hypothesis that glutamate is the excitatory neurotransmitter. Complete abolition of the response to nerve stimulation required an exposure to 10 mM glutamate

Fig. 2 Effect of nerve stimulation of varying duration on isometric tension (a) and on cyclic GMP content (b) of giant barnacle muscle. The time scale applies to parts A and B of the tension record as well as to the cyclic GMP data. a, A, Isometric tension response to a single stimulus train applied to the motor nerve. An individual train consisted of 10 pulses delivered at 100 Hz; each pulse was supramaximal in amplitude and 1 ms in duration. a, B, Isometric tension response when such a stimulus train was applied repetitively (once per second for 2 min). b, Each point shows the mean percentage ($\pm$ s.e.m.) of cyclic GMP in stimulated muscles compared with control muscles (calculated as described in Fig. 1). Stimulus conditions were identical to those for a, B. After stimulating the nerve for the indicated periods of time, the muscles (both stimulated and control) were homogenised and further processed as described in Fig. 1.

for 1 h. (This slow time course does not seem unreasonable since many of the individual fibres of the muscle are not directly exposed to the bathing solution and since many of the neuromuscular junctions of individual fibres lie at the bottom of deep, narrow clefts¹⁵.) After neuromuscular transmission was blocked with 10 mM glutamate, stimulation of the motor nerve no longer caused an increase in muscle cyclic GMP level (Table 1, C1). This observation suggests that the nerve-induced (Table 1, A1) increase in cyclic GMP requires the activation of glutamate receptors by the neurotransmitter. KCl depolarisation, however, was still able to increase the cyclic GMP level in glutamate-desensitised muscles (Table 1, C2). This finding indicates that the KCl-induced increase in cyclic GMP is not a result of depolarisation-dependent release of glutamate from the nerve terminals. The simplest hypothesis that could account for the increase in cellular cyclic GMP produced by nerve stimulation and KCl depolarisation, as well as for the fact that the KCl-induced increase required Ca^{2+} , is that both types of contractile stimuli increase cyclic GMP by causing Ca^{2+} influx across the muscle membrane.

In the barnacle, as well as in a number of other systems, receptor activation by the appropriate hormone or neurotransmitter is associated with increased cyclic GMP and a physiological response. In some systems, cyclic GMP seems to serve as a causal link between receptor activation and the physiological response. For example, muscarinic cholinergic agonists increase cyclic GMP levels in the heart¹ and in sympathetic ganglia⁵, and exogenous derivatives of cyclic GMP are able to mimic some of the physiological effects of muscarinic agonists in these preparations^{16,17}. In certain other systems in which hormonal elevation of cyclic GMP has been observed, Ca^{2+} seems, however, to link stimulus to response^{3,4,8-8}. It seems likely that the barnacle muscle is one of these latter systems and that calcium rather than cyclic GMP is the agent which directly activates the contractile machinery.

Table 1 Effect of nerve stimulation and of KCl depolarisation on cyclic GMP in giant barnacle muscle in various conditions

Pre-incubation	Stimulation	% Control
A, Control saline	1. Nerve stimulation	227 ± 44 (7)
	2. 100 mM KCl-saline with Ca^{2+}	298 ± 39 (23)
B, Ca^{2+} -free saline	1. 100 mM KCl without Ca^{2+}	99 ± 5 (8)
	2. 100 mM KCl with Ca^{2+}	370 ± 49 (11)
C, Glutamate saline	1. Nerve stimulation	119 ± 13 (5)
	2. 100 mM KCl-glutamate-saline	267 ± 60 (18)

A, Muscles were dissected, and pre-incubated for 1–3 h, in control barnacle saline, as described in Fig. 1. Control muscles were then incubated for an additional 2 min in control barnacle saline; stimulated muscles were incubated for 2 min in 100 mM KCl-barnacle saline or were stimulated through their motor nerve as described in Fig. 2.

B, Muscles were dissected and washed with Ca^{2+} -free barnacle saline (equimolar replacement of the Ca^{2+} in the control saline with Mg^{2+}) and incubated for 2–3 h at 4 °C, with two changes of fresh Ca^{2+} -free saline. Control muscles were then incubated for an additional 2 min in Ca^{2+} -free saline; stimulated muscles were incubated for 2 min in Ca^{2+} -free 100 mM KCl-saline or for 2 min in Ca^{2+} containing 100 mM KCl-saline.

C, All muscles were pre-incubated for 1–3 h at 4 °C in control barnacle saline, and then incubated for an additional hour at 20 °C in barnacle saline plus 10 mM monosodium glutamate ('glutamate saline'). Control muscles were then incubated for an additional 2 min in glutamate saline. Stimulated muscles were either maintained for 2 min in glutamate saline, during which time the motor nerve was stimulated as described in Fig. 2, or else were incubated for 2 min in 100 mM KCl-saline containing 10 mM monosodium glutamate.

Data: mean value ± s.e.m. (number of individual experimental muscles).

Control levels of cyclic GMP were: A, 75 ± 8 ($n = 34$); B, 43 ± 4 ($n = 16$); C, 62 ± 6 ($n = 18$) fmol per mg protein. Note that the basal cyclic GMP level in muscles pre-incubated in Ca^{2+} -free barnacle saline (B) was only about half that of muscles pre-incubated in normal saline (A).

Since Ca^{2+} entry seems to be responsible both for the activation of contraction in the barnacle, and for the increase in cyclic GMP, the problem remains as to the function of the cyclic GMP increase associated with contractile activity in the muscle fibres of the barnacle. One possibility^{18,19} is that cyclic GMP is involved in regulating Ca^{2+} metabolism. Ong and Steiner²⁰ have suggested that cyclic GMP may have a role in the regulation of myosin function. Another possibility worth considering is that cyclic GMP has a role in activity-dependent control of the expression of the muscle genome. In mammalian skeletal muscle, for example, muscle activity can prevent the appearance of denervation-induced extrajunctional acetylcholine receptors²¹. In preliminary experiments, we have found that contractile activity in vertebrate skeletal muscle is associated with an increase in cyclic GMP level.

We thank Dr J. R. Sanes for drawing our attention to the advantages of the giant barnacle muscle as a preparation for studying cyclic nucleotide physiology. This research was supported by the USPHS.

Development of cholinergic characteristics in adrenergic neurones is age dependent

OBSERVATIONS from several laboratories indicate that neurones from adrenergic ganglia cultured from rats during the perinatal period may, in certain culture conditions, develop several clearly cholinergic characteristics. These cultured neurones may form cholinergic synapses among themselves as well as on cocultured striated muscle^{1–3}, and the cell population developing cholinergic mechanisms derives from an initially adrenergic neuronal population as a gradual shift in synaptic vesicle cytochemistry occurs together with increasing choline acetyltransferase (ChAc) activity and an increasing number of cholinergic synaptic interactions between neurones^{4,5}. In certain conditions these cultured neurones may release both noradrenaline and acetylcholine⁶. We address here the question of whether this unexpected ability of the adrenergic neurone to develop cholinergic mechanisms in culture derives from the neurone's response to some novel aspect of the tissue culture system

or is instead the *in vitro* expression of a developmental period during which the automatic neurone *in vivo* is in a labile state of differentiation. Our results favour the latter explanation.

These experiments were made possible by two developments. First, small explants of superior cervical ganglia (SCG) were successfully cultured from increasingly older

Fig. 1 *a*, Variation of DOPA-decarboxylase (DDC) activity in SCG explants with time in culture. Ganglia were obtained from 15½-d (△) and 20-d (□) day embryonic and 2-d (■), 5-d (▲), 22-d (●) (not shown), and 200 (●) day postnatal rats. Explants of approximately equal size were obtained by culturing the entire 15½-d embryonic ganglion and by dividing the increasingly larger, more mature ganglia into pieces of similar size. Explants were placed on to 24-mm Aclar dishes and fed three times weekly with medium containing 65% Eagle's minimum essential medium with glutamine added, 25% human placental serum (HPS) 10% chick embryo extract (EE), 3% 1.1 M glucose, and 25 units ml⁻¹ nerve growth factor. These levels of HPS and EE have been shown to foster the development of cholinergic properties in cultures of SCG neurones⁷. At the times indicated, cultures were rinsed with Leibovitz medium and, after carefully blotting excess medium, were frozen and stored at -80 °C. Cultures were freeze-dried under vacuum at -40 °C (ref. 18) for 3 d. Explants were dissected free from supporting cell and neurite outgrowth and from the collagen, weighed using a quartz-fibre balance¹⁸, and homogenised in 36 µl of 50 mM sodium phosphate buffer (pH 7.6) containing 0.1% bovine serum albumin and 0.1% Triton X-100. Intact ganglia for *in vivo* (or zero time) enzyme activities were treated in the same way except that ganglia from older animals were homogenised in larger volumes in order to keep the weight-volume ratio constant. Homogenates were stored at -80 °C until as said. DDC activity was determined by a modification of the method of McCaman *et al.*¹⁹. Enzyme activity is expressed relative to dry weight of the explant ± s.e.m. There were no significant differences between weights of explants from different age rats after the same time in culture. The DDC activity in explants from postnatal animals after 30 d in culture stabilises at about 70% of the activity in the adult ganglia *in vivo*. Studies of thionin-stained explants are in progress to determine the number of neurones in explants from different age animals after 40 days in culture. *b*, Variation of choline acetyltransferase (ChAc) activity in SCG explants with time in culture. ChAc activity was determined by a modification²⁰ of published methods^{21,22} on the same homogenates described above. Enzyme activity is expressed relative to dry weight of the explant ± s.e.m. Activity at zero time is the *in vivo* activity in the ganglion.

rats, including adult. A similar pattern of ChAc development was seen in SCG from perinatal rats regardless of whether explants or dissociated neurones were studied⁷. Second, we observed that ChAc, the enzyme synthesising acetylcholine and highly localised to cholinergic neurones, is present only in extremely low amounts in all cultures freshly prepared from rat SCG (after degeneration of the pre-ganglionic endings). Thus it was possible to measure ChAc accrual in cultures from adrenergic ganglia prepared at ages between the 15-d embryo and the adult rat. Our results indicate that the ability of SCG explants to develop cholinergic characteristics reaches a maximum at approximately the second postnatal day; beyond the third postnatal week this 'shift' does not occur.

Explants of approximately equal size were prepared from SCG of rats of different ages, cultured in the presence of NGF for 1 month or longer and then assayed for activities of ChAc and of DOPA-decarboxylase (DDC) (details in Fig. 1 legend). The latter enzyme, in the synthetic pathway of catecholamines, is localised to adrenergic neurones in the SCG⁸⁻¹⁰. The cytochemistry of the synaptic vesicle population was studied in cultures from 5-d pups and from adult rats after 1 month in culture by methods previously described⁴.

The pattern of change in DDC activity with time in culture was related to whether the explant was taken from a prenatal or a postnatal rat (Fig. 1*a*). DDC activities in SCG explants from 15½-d and 20-d embryos increased during the first 3 d in culture, then decreased during the following 4 weeks. DDC activities in SCG explants from 2, 15, and 22-d (not shown) pups and from adults first decreased, then levelled or increased during the next 4 weeks, beyond which time there were no significant differences between these explants.

The specific activity of ChAc in SCG explants fell during the first 3-4 d in culture (Fig. 1*b*), probably because of degeneration of presynaptic terminals, then increased during the next 4 weeks in all explants except those taken from the 22-d pup (not shown) and the adult animal. The enzyme activity attained by SCG explants from animals of different ages differed significantly after 1 month in culture; the highest activity was in explants from 2-d pups and the lowest activity was in explants from adults.

The variation with rat age of DDC activity in SCG explants after 1 month in culture differed considerably from the variation in ChAc activity in the same explants (Fig. 2). The accrual of DDC activity by SCG explants increased as explants were taken from progressively older

Fig. 2 Activities of DDC and ChAc in SCG explants after 1 month in culture plotted against the age of the rat at the time of explantation. All values for 30 and 45 day points in Fig. 1 for each age were averaged to obtain as large a statistical population as possible. Values for explants from 15½-d and 20-d embryos, for 2, 5, 15, and 22 day pups, and for adult animals represent averages ± s.e.m. of 3, 8, 31, 43, 55, 23, and 15 explants, respectively.

animals from the 15½-d embryo to the 2-d pup; explants from animals aged 2 d or older showed no significant differences in the DDC activity after 30 d or more in culture. The ChAc activity after 30 d in culture was higher as explants were taken from progressively older animals from 15½-d prenatal to 2-d postnatal; but the ability of explants from older animals to develop ChAc activity *in vitro* decreased. The ChAc activity in SCG explants cultured from adult animals did not increase at all, the activity after 45 d being significantly less than the activity remaining 4 d after denervation.

In interpreting these data, we must consider the possibility that our culture system selects certain neurones present in the neonatal animal that are already committed to cholinergic. We have presented biochemical, physiological and cytochemical evidence against this view^{4,5}. In the data presented here, we note no significant differences between the ChAc activities in explants from animals of any age 3 to 5 d after denervation (Fig. 1b, and 5-d and 22-d pups not shown), indicating that no cholinergic cells are present at the time of explantation in neonatal SCG that are not present in the adult. The high level of DDC activity in all explants from postnatal animals (Fig. 2) indicates a good state of neuronal viability, and thus the change with rat age (at explantation) in the accrual of ChAc activity *in vitro* must reflect a difference in the neuronal synthesis of ChAc rather than a difference in survival of selected neuronal populations.

The cytochemistry of vesicles within axonal varicosities was consistent with the ChAc data. Vesicles of varicosities in the outgrowth of SCG explants from 5-d pups were

Fig. 3 Electron micrographs of vesicle-containing varicosities found in cultures of SCG explants taken from *a*, 5-d-old rat pups and *b*, adult rats. The cultures were companions to those used for the biochemical analyses (see Fig. 1 legend) and were fixed after 28–33 d *in vitro*. After an initial rinse in Leibovitz medium (L-15) the cultures were incubated 30 min in 10^{-6} M noradrenalin in L-15 to which ascorbic acid (0.2 mg ml^{-1}) was added. The pH was adjusted to 7.2–7.3 before incubation. A rinse in L-15 was followed by fixation with 3% KMnO_4 in Krebs's Ringer phosphate (pH 7.1, 4°C) and by *en bloc* staining with 1% uranyl acetate in maleic acid buffer (pH 5.2, 4°C). Embedding in Epon-Araldite followed dehydration. Scale bar represents $0.3 \mu\text{m}$.

Fig. 4 No. of profiles (ordinate) containing listed percentages of dense-cored vesicles (abscissa) in 28–33-d cultures of SCG from 5-d rat pups and adult rats. Consecutive varicosities, similar to those illustrated in Fig. 3, were photographed and printed at a standard magnification. Vesicles measuring 40–70 nm were counted and classified as dense-cored or clear. Twenty-five profiles from each group are charted. Total vesicles per profile ranged from 9 to 38 and 9 to 54 in the groups taken from 5-d pups and adults respectively.

predominantly clear, whereas the majority of the vesicles of varicosities in explants from adult animals were dense-cored (Fig. 3). This difference is illustrated graphically in Fig. 4. Only 1 of 25 profiles from 5-d pup cultures contained 60–70% dense-cored vesicles and 22 of 25 contained less than 10%. In contrast profiles found in adult rat SCG cultures contained no less than 50% dense-cored vesicles and 17 of 25 contained over 80%.

These data demonstrate that the developmental age of the rat adrenergic neurone determines whether this neurone can adjust its transmitter mechanisms and express in culture two well established characteristics of cholinergic neurones—ChAc activity and clear synaptic vesicles. The dramatic decrease in the ability of SCG explants taken from rats beyond 2 to 5 d postnatal to accrue ChAc activity in culture (Fig. 2) suggests that at this stage in their *in vivo* development sympathetic neurones of the SCG receive important information related to the expression of transmitter mechanisms. A critical event during the differentiation of these neurones apparently begins about 2 d postnatally; the result of this event is a commitment to being adrenergic.

Although these experiments do not rule out the possibility that preganglionic connections influence the expression of cholinergic or adrenergic mechanisms in the sympathetic neurone, available information is more supportive of the view that the target organ, containing adrenergic receptors and perhaps trophic signals (other than nerve growth factor) finally determines the appropriate neurotransmitter these neurones synthesise (ref. 11 for review). The innervation of target organs by the rat SCG is incomplete at birth. Studies involving electron microscopy¹², histochemical fluorescence¹³, norepinephrine uptake¹⁴, and changes in tyrosine hydroxylase activity¹⁵ indicate that sympathetic innervation in iris begins 2–3 d postnatally and that mature innervation in iris is not achieved until 3–4 weeks after birth; in the pineal, mature innervation is not observed until 2–3 weeks after birth^{16,17}. Our tissue culture observations suggest that a signal, most likely from the adrenergic target organ, begins its influence about the second postnatal day in the rat and that this signal ensures the commitment to adrenergic function which characterises most sympathetic neurones *in vivo*.

Phosphorylation of acetylcholine receptor by endogenous membrane protein kinase in receptor-enriched membranes of *Torpedo californica*

THE molecular basis of synaptic transmission is a fundamental problem in neurobiology. Although neurotransmitters produce striking changes in post-synaptic ion permeability, little is known about the molecular events following binding of neurotransmitter to its receptor. It has been postulated that the effects of neurotransmitters on post-synaptic membranes are mediated by changes in protein phosphorylation^{1,2}. There has been no direct evidence for neurotransmitter-dependent changes in protein phosphorylation in membranes prepared from innervated tissues, however. We investigated this problem using an acetylcholine receptor-enriched membrane fraction prepared from the electric organ of *Torpedo californica* and found that several membrane polypeptides are phosphorylated when this fraction is incubated with γ -³²P-ATP and 100 mM K⁺ (ref. 3). In particular, we demonstrated that a polypeptide of 65,000 molecular weight (MW) is phosphorylated and that phosphorylation of this and other polypeptides is inhibited by cholinergic ligands. A 65,000 MW polypeptide in the same membrane preparation also reacted with antibody prepared against the purified acetylcholine receptor. This suggested that a component of the acetylcholine receptor itself could be phosphorylated by an endogenous membrane protein kinase. Here we present proof that the 65,000 MW component of the acetylcholine receptor is a substrate for an endogenous membrane protein kinase.

Membranes enriched 15-fold in acetylcholine receptors were prepared from the electric organ of *T. californica* as described previously³. Figure 1a shows the polypeptide composition of the acetylcholine receptor-enriched membranes. This fraction contains endogenous protein kinase activity which maximally phosphorylates four polypeptides in the presence of 5 μ M ATP, 100 mM K⁺ and 0.005% Triton X-100 (ref. 3). To prove that a component of the acetylcholine receptor is phosphorylated by the endogenous protein kinase, phosphorylation of the acetylcholine

receptor was studied using two-dimensional immunoelectrophoresis as described by Converse and Papermaster⁴. Acetylcholine receptor-enriched membranes were incubated with γ -³²P-ATP and electrophoresed in sodium dodecylsulphate (SDS) polyacrylamide gels as described in Fig. 1. The gels were cut into longitudinal strips along the sample wells; one gel was stained for protein, another was subjected to immunoelectrophoresis at right angles into Agarose containing anti-acetylcholine receptor serum. Polypeptides derived from the acetylcholine receptor which are present in optimal concentrations form immunoprecipitates with the anti-acetylcholine receptor antibody and are recognised as 'rockets.' Figure 1b shows one major Coomassie blue stained 'rocket' which corresponds to the immunoprecipitate formed by the reaction of the antiserum with the 65,000 MW polypeptide of the acetylcholine receptor. Control gels run against pre-immune serum show no 'rockets.' Autoradiography of the dried gel could be used to determine whether the immunoelectrophoretic 'rocket' is radioactive. Figure 1c demonstrates that the same polypeptide precipitated by anti-acetylcholine receptor serum contains ³²P. Two other components of the acetylcholine receptor also react with antiserum and contain minor amounts of ³²P. Their polypeptide-antiserum concentration ratios are, however, not optimal for adequate resolution of the corresponding 'rockets.' This experiment provides firm evidence that the 65,000 MW component of acetylcholine receptor is phosphorylated by an endogenous membrane protein kinase present in receptor-enriched membranes. The major immunoprecipitate consists only of antibody against the acetylcholine receptor and the 65,000 MW component of the receptor⁴. Therefore, ³²P

Fig. 1 Two-dimensional immunoelectrophoresis of acetylcholine receptor-enriched membranes. Acetylcholine receptor-enriched membranes were prepared from the electric organ of *T. californica* as previously described³. Membranes were incubated for 0.5 min at 0 °C in γ -³²P-ATP (1-2 μ Ci per tube), 0.25 mM EGTA, 10 mM MgAc₂, 0.0625 M Tris-HCl pH 6.8 and 100 mM KCl. The reaction was stopped by the addition of SDS to a final concentration of 4% and mercaptoethanol was added to a final concentration of 5%. Electrophoresis of 50 μ g and 75 μ g of membrane protein in SDS polyacrylamide slabs was carried out according to the method of Laemmli⁵ with 8% acrylamide in the running gel and 3% in the stacking gel. The slabs were run overnight at 8 mA per gel. The gels were then cut into longitudinal strips. *a*, The strip containing 50 μ g of membrane protein was simultaneously fixed and stained for protein for 2 h in 25% isopropanol, 10% acetic acid and 0.2% Coomassie blue and destained overnight in 25% isopropanol, 10% acetic acid. *b*, *c*, The strip containing 75 μ g of membrane protein was electrophoresed at right angles to the original direction into two layers of Agarose⁴, the first containing 1.5% Lubrol PX (Sigma) and the second containing 16% goat anti-acetylcholine receptor antiserum. Antiserum was prepared against purified *T. californica* receptor as previously described³. Immunoelectrophoresis was run at a constant voltage of 53 V (measured across the gel) for 2 h at 4 °C. The acrylamide strip and the Agarose layer were then removed to minimise electroosmotic effects. Agarose containing buffer⁴ was used to replace the removed layers. Immunoelectrophoresis was resumed for an additional 4 h at 53 V. The Agarose gels were then incubated overnight to remove unreacted serum, in 10 mM NaPO₄ pH 7.4, containing 150 mM NaCl, dried and stained and destained as described above (*b*). The gels were subjected to autoradiography on Kodak NS2T X-ray film for 5 weeks (*c*). Arrow represents MW of 65,000.

present in this 'rocket' must be derived from a phosphorylated component of the acetylcholine receptor.

In summary, we have found that the acetylcholine receptor is a substrate for an endogenous membrane protein kinase. We have recently demonstrated that phosphorylation of receptor-enriched membranes is regulated by cholinergic ligands³. Moreover, phosphorylation of the receptor may account for the observation that the acetylcholine receptor exists in two forms with different isoelectric points^{5,6}. Taken together these findings suggest that phosphorylation of the receptor may play an important role in post-synaptic events. Rhodopsin also is an extensively purified membrane protein which undergoes phosphorylation regulated by its physiological stimulus; this molecule is phosphorylated in the presence of light and ATP^{7,8}. It has been suggested^{7,8} that phosphorylation of rhodopsin might be related to a decrease in Ca²⁺ ion permeability. Furthermore, it has been shown that light-stimulated phosphorylation of rhodopsin is due to a direct conformational change of the visual pigment and not due to an effect of light on protein kinase activity. By analogy, changes in the phosphorylation of the acetylcholine receptor might be the result of conformational changes in the receptor protein induced by cholinergic ligands³. Phosphorylation could have a role in regulation of ion permeability or in other postsynaptic phenomena such as desensitisation, maintenance of the receptor at the synapse, trophic effects of innervation, and appearance of extra-junctional receptors after denervation. The finding that the acetylcholine receptor itself is phosphorylated provides a new avenue for investigation of these possibilities.

In vitro phosphorylation of the acetylcholine receptor

In a study of the properties of the acetylcholine receptor protein (AChR) solubilised from extrasynaptic and subsynaptic areas of rat diaphragm, Brookes and Hall¹ reported differences in the behaviour of these receptors on isoelectric focusing and concluded that extrasynaptic and subsynaptic receptors "have similar properties but are still distinct molecules". Applying the same technique to crude detergent extracts of membrane fragments from *Electrophorus electricus* electric organ², we also found two forms of AChR with isoelectric points similar to those reported by Brookes and Hall. Furthermore a catalytic inter-conversion between these two forms was achieved by incubating *in vitro* the membrane extract in the presence of 100 mM NaCl or 100 mM NaF. This finding was interpreted as resulting from a phosphorylation-

dephosphorylation of the AChR. In agreement with this interpretation, it has been shown³ that endogenous protein kinase and phosphoprotein phosphatase activities are indeed present in membrane fragments isolated from the electric organ of *E. electricus*. We report here that in detergent extracts of these membrane fragments, a phosphorylation of AChR takes place when incubated in the presence of γ -³²P-ATP, Mn²⁺ and the endogenous protein kinases.

Membrane fragments were prepared by homogenising fresh or frozen electric tissue (40 g) into 80 ml of PNM (10⁻⁴M phenylmethylsulphonylfluoride, 0.02% NaN₃, 0.014 M 2-mercaptoethanol in H₂O, pH 6.2) for 5 min at 0 °C using a Virtis blender at medium speed. This homogenate was centrifuged for 30 min, 20,000g at 4 °C and the pellet resuspended in 20 ml PNM. The extraction of AChR was carried out by gently stirring the resuspended membrane fragments in the presence of 5% Triton X-100 for 60 min at room temperature. The suspension was then centrifuged at 100,000g for 60 min, at 4 °C and the supernatant ('detergent extract') collected and kept at 4 °C. The AChR was assayed with ³H- α -toxin (12.4 Ci mmol⁻¹) from *N. nigricollis*⁴; 80-100 pmol of AChR were present per ml of detergent extract. Phosphorylation of AChR was carried out by incubating the detergent extract for 30 min at room temperature in the presence of 100 mM Tris, 10⁻³M ouabain, 10 mM MnCl₂, 100 mM NaF and 4 μ M γ -³²P-ATP (16 Ci mmol⁻¹ purchased from Amersham) at pH 7.4 in a total volume of 1 ml. This mixture was then applied on top of a Sephadex G-50 column (46 cm $\times$ 2.2 cm) equilibrated and eluted in 20 mM Tris, 0.1% Triton X-100, 50 mM NaF, 10⁻⁴M phenylmethylsulphonylfluoride, 0.02% NaN₃ at pH 7.4. The protein fraction eluted in the void volume was pooled into a dialysis bag and concentrated at room temperature over polyethyleneglycol powder. The content of the dialysis bag was then removed, centrifuged for 3 min at 2,000g 4 °C and the supernatant ('phosphory-

Fig. 1 Crossed-immunoelectrophoresis was carried out on Agarose gel. 15 ml of a 1% solution of Indubiose A45 in 24.5 mM veronal, 0.48 mM calcium lactate, 2 mM NaN₃, 1% Triton X-100, 73 mM Tris-HCl, pH 8.6, were poured on a 10 cm $\times$ 8.5 cm glass plate. After congelation, a 3 cm $\times$ 3 cm gel slab was then cut out in the middle of the plate and replaced with 1.6 ml of the above gel solution containing 25-50 μ l of anti-AChR serum. A 3 mm $\times$ 6 mm well is then punched in the lower left of the antibodies containing gel for the application of 10-30 μ l of antigen solution. The electrophoresis in the first dimension is carried out at 15 °C for 45 min at 10 V cm⁻¹ in the above Tris-veronal buffer pH 8.6. Anode to the right. The second dimension is carried out at 15 °C for 16-20 h at 2 volts cm⁻¹ with the anode at the top. After electrophoresis, the gel is pressed under several layers of blotting paper and a weight of about 10 g cm⁻², washed several times in 20 mM Tris-HCl, 0.1 M NaCl, 0.1% Triton X-100, pH 7.4, pressed again and finally washed in H₂O and dried. The dry gel is stained with 0.5% Coomassie blue in ethanol-acetic acid-H₂O (4.5/1/4.5) and destained in ethanol-acetic acid-H₂O (4.5/1/4.5). The destained gel is washed in H₂O and dried. It is then placed in contact with a Kodak Kodirex film. The autoradiogram is developed 1-2 d later. *a*, Coomassie blue staining of the precipitation line(s) between anti-AChR antibodies and ¹²⁵I- α -bungarotoxin-AChR complex. 20 μ l of detergent extract containing 1.8 pmol AChR and 1.5 pmol of ¹²⁵I- α -bungarotoxin (238 Ci mmol⁻¹) were applied. Anti-AChR antiserum was at a density of 5 μ l of serum per cm². *b*, autoradiograph of (*a*) after 24-h exposure.

Fig. 2 Crossed-immunoelectrophoresis. Conditions as described in Fig. 1. *a*, Anti-AChR antibodies and phosphorylated detergent extract. 1.1 pmol of AChR in 18 μ l were applied. Anti-AChR antiserum was at a density of 4.5 μ l of serum per cm^2 . *b*, Autoradiograph of (*a*) after 24-h exposure. *c*, Anti-bovine serum albumin antibodies and bovine serum albumin (large peak) and anti-AChR antibodies and phosphorylated detergent extract. 1.3 pmol of AChR and 15 pmol bovine serum albumin were applied in 20 μ l. Anti-AChR and anti-bovine serum albumin antisera were respectively at a density of 3.3 and 0.55 μ l of serum per cm^2 . *d*, Autoradiograph of (*c*) after 48-h exposure.

lated detergent extract') was removed and kept at 4 °C. Rabbit sera (anti-AChR) were raised against Triton X-100 extracted AChR purified from *E. electricus* membrane fragments by affinity chromatography³. The purified AChR was analysed by dodecylsulphate polyacrylamide gel electrophoresis and found to be composed of three polypeptides of molecular weights of 43,000, 49,000 and 59,000.

To demonstrate the phosphorylation of the receptor protein, crossed-immunoelectrophoresis⁶ was used to identify and separate the AChR from the bulk of the proteins and lipids present in the detergent extract. The anti-AChR antiserum was first assayed against an aliquot of detergent extract preincubated with ¹²⁵I- α -bungarotoxin (238 Ci mmol^{-1}). Only one precipitation line was observed both by Coomassie blue staining and by autoradiography (Fig. 1*a, b*). When the phosphorylated detergent extract underwent crossed-immunoelectrophoresis in a 1% Agarose gel containing anti-AChR antibodies, again only one precipitation line was seen both by Coomassie blue staining and by autoradiography (Fig. 2*a, b*). A nonspecific absorption of phosphorylated proteins on the AChR-anti AChR precipitate could, however, be the cause of the line seen by autoradiography (Fig. 2*b*). To test this possibility, a mixture of 'phosphorylated detergent extract' and bovine serum albumin was submitted to crossed-immunoelectrophoresis in a gel containing both anti-AChR and anti-bovine serum albumin antibodies. This time, two precipitation lines were stained by Coomassie blue: one corresponded to the AChR, the other to bovine serum albumin. Only the line characteristic of the AChR was detected by autoradiography, however, (Fig. 2*c, d*), indicating without ambiguity that the AChR had been phosphorylated.

To determine which polypeptide chains of the purified AChR had been phosphorylated, AChR-anti-AChR precipitates obtained from crossed immunoelectrophoresis were cut out of agar-coated plates, solubilised in 2% sodium dodecylsulphate, 3% mercaptoethanol, 0.062 M Tris at

pH 6.8, and analysed by dodecylsulphate polyacrylamide gel electrophoresis and autoradiography. Only one polypeptide of apparent molecular weight 48,000 could be clearly detected on the densitogram obtained after scanning of the autoradiograph (Fig. 3).

The AChR protein purified from *E. electricus* gives two (ref. 5) or three (ref. 7 and A.S., unpublished) bands by polyacrylamide gel electrophoresis in sodium dodecylsulphate but only one of them corresponding to a polypeptide chain of apparent molecular weight $43,000 \pm 3,000$ is labelled by ³H-MBTA⁷ or ³H-MPTA (A.S., unpublished), two covalent affinity labels of the acetylcholine receptor site. Interestingly, it is not this chain which is phosphorylated *in vitro* but that of apparent molecular weight $48,000 \pm 3,000$.

Fig. 3 Densitogram obtained from the autoradiograph of precipitates between anti-AChR antibodies and phosphorylated detergent extract after sodium dodecylsulphate polyacrylamide gel electrophoresis. Precipitates from several immunoelectrophoresis were cut out from dried Agarose plates after Coomassie blue staining and solubilised in a buffer containing 0.062 M Tris-HCl, 2% sodium dodecylsulphate, 3% 2-mercaptoethanol at pH 6.8. Electrophoresis was carried out on a 10% acrylamide slab gel of 1.5-mm width following the method of Laemmli¹¹ modified by Anderson and Gesteland¹². The gel was stained for protein with Coomassie blue, destained, washed in H_2O , dried and placed in contact with Kodak Kodirex film. The film was developed after 120 h. The densitometric scanning of the autoradiograph was carried out using a Vernon scanner and the optical density was expressed in arbitrary units. The following proteins were used as markers for molecular weight determination; 1, bovine serum albumin; 2, catalase; 3, albumin; 4, aldolase; 5, chymotrypsinogen. The band of 48,000 molecular weight could not be detected by Coomassie blue staining.

As the *in vitro* phosphorylation-dephosphorylation of the AChR takes place under conditions close to those needed for the interconversion between the two 'isoelectric' forms of the AChR, one may relate these reactions to at least two different regulatory mechanisms. (1) For instance, the 48,000 molecular weight polypeptide is the ionophore and its transport properties are regulated by phosphorylation-dephosphorylation reactions as proposed by Greengard⁹. The differences in isoelectric points between extra- and subsynaptic receptors would simply result from the fact that only the subsynaptic AChR is activated by the neurotransmitter and therefore phosphorylated. (2) In relation with the theory on selective stabilisation of developing synapses¹⁰, the phosphorylation of the AChR could be an element of the complex 'stabilisation reaction' postulated to cause the interconversion of the labile and mobile form of the AChR present in extrasynaptic areas into its stable and immobile form in the mature subsynaptic membrane. If this reaction was indeed taking place in *E. electricus* electric organ despite the fact that it is not an embryonic

system, then the phosphorylated 48,000 molecular weight chain would not necessarily represent the ionophore but could for instance be involved in the aggregation of the receptor oligomer and/or its protection against proteolysis.

We thank Dr H. Betz for a gift of ^{125}I - α -bungarotoxin and for suggestions and comments and Drs P. Courrège, A. Danchin and J. M. Lasry for discussions. This work was done during the tenure of a research fellowship of Muscular Dystrophy Associations of America to V.I.T. and supported by the CNRS, INSERM, DGRST, CEA and Collège de France.

Association of DNA synthesis with the nuclear membrane in sea urchin embryos

THERE is considerable evidence implicating the cell membrane as the site for DNA replication in prokaryotic systems^{1–3}. Several laboratories have considered the possibility that the nuclear membrane may serve a similar role in eukaryotes. This model has been supported by biochemical studies in various eukaryotic cell systems^{4–8}. But, autoradiographic analyses in mammalian cells, that previously indicated that DNA synthesis was initiated at the nuclear membrane^{9,10}, now provide the strongest evidence against an involvement of the nuclear membrane in DNA synthesis^{11–13}. The sea urchin system presents several advantages for studies of DNA synthesis. On fertilisation a population of dormant unfertilised eggs begins a series of very rapid cellular divisions, the first three of which are naturally synchronous. Biochemical studies with this system have suggested that rapid replication of DNA occurs at a nuclear membrane site and that DNA may be associated with the site only during the period of DNA synthesis¹⁴. We therefore decided to undertake an autoradiographic study in the sea urchin embryo. The results presented here strongly support the role of the nuclear membrane in the synthesis of DNA.

We examined DNA synthesis during the S-phase immediately following first cleavage. In agreement with Hinegardner *et al.*¹⁵, we found that DNA synthesis begins in mid-telophase, a stage in which each chromosome is encased in its own double membrane vesicle, termed a karyomere (Fig. 1a). The grain distribution in embryos pulsed at this time for either 30 or 60 s showed a peripheral labelling pattern within each karyomere (Fig. 1a, b). A quite different distribution of grains was obtained if, instead of a short exposure to thymidine, the embryos were incubated for a longer period. After 5 min of labelling (which in this system is more than $\frac{1}{3}$ of the S-period), there was an increased number of grains in the central area of the karyomere (Fig. 1c). Although there was still dense incorporation at the periphery, the result demonstrates that chromatin is not confined to the periphery.

It is important to make certain that the grains represent incorporation of labelled nucleotide into DNA. Thymidine is

incorporated into acid precipitable material which is resistant to digestion in alkali, and is DNase labile. Also embryos exposed to label before the S-phase, and even into early telophase, showed no radioactive incorporation when assayed by autoradiography. Finally, there is virtually no background of grains appearing in the cytoplasmic areas even after long periods of incorporation.

Figure 1 shows that increased exposure to label during the S-phase results in an increase in grains appearing in the centre of the karyomere and subsequent nuclei. This indicates that either (1) the location of DNA relative to the membrane is stable and the replication machinery begins synthesis at the

Fig. 1 Labelling of karyomeres for a, 30 s; b, 90 s, and c, 5 min following the start of S phase. Gametes from the Pacific sea urchin, *Strongylocentrotus purpuratus* were obtained by injecting 0.55 M KCl into the coelomic cavity to induce shedding. The eggs were washed, fertilised, and incubated at 16 °C as previously described¹⁴. At 100 min after fertilisation (the start of the second DNA synthetic period¹⁵) radioactive thymidine (methyl- ^3H ; New England Nuclear; 50 Ci mmol⁻¹) was added to a final concentration of 5 $\mu\text{Ci ml}^{-1}$. Samples were removed at the times indicated and the pulse stopped by the addition of an equal volume of Karnofsky's fixative. After settling, the labelled embryos were resuspended in fresh fixative, allowed to sit for 2 h, and postfixed for an additional hour in 1% osmium tetroxide. Following ethanol dehydration, the fixed embryos were embedded in Epon resin and sectioned on an LKB ultramicrotome. Purple/gold sections were removed from the air/water interface using Formvar coated copper grids and stained with uranyl acetate and lead citrate, then carbon coated under vacuum. The grids were coated with Ilford L-4 emulsion (Polysciences) using the technique of Stevens²⁴ and stored at -60 °C for 14 d–6 months. After development, the grids were routinely restained with lead citrate. Micrographs were made using a Philips 300 electron microscope. The bar in each figure represents 1 μm .

Fig. 2 Distribution of grains in nuclei labelled for various periods of time. *a*, Nucleus of embryo labelled continuously for 20 min beginning at 100 min after fertilisation. *b*, Embryos pulsed for 30 s, washed twice in normal sea water, and then resuspended in normal sea water containing 200 μ M unlabelled thymidine. The chase period was for 4.5 min. *c*, Embryos pulsed for 30 s and chased for 20 min in cold thymidine as in *b*. Embryos were labelled with ^{3} H-thymidine, fixed, and prepared for autoradiography as described in Fig. 1.

periphery and moves into the central area, or (2) nascent DNA is displaced from a stable site of replication at the periphery and moves into the centre. To distinguish between these two possibilities we looked at the distribution of continuously labelled DNA after the completion of the S-phase and the fate of the DNA synthesised during early S using a pulse-chase analysis. A typical result of the first study is shown in Fig. 2*a*. The pattern of grains seen in nuclei after 20 min of labelling indicates a concentration of radioactive DNA within the central areas and little or none present at the periphery (Fig. 2*a*). Under such conditions the DNA is uniformly labelled and the embryos are no longer in the S-phase. This shows that once replication is completed, virtually all of the DNA is displaced away from the membrane region; and that most of the DNA is not permanently associated with the membrane. A pulse-chase analysis supports these conclusions. Nuclei of embryos pulsed during the first 30 s of the S-phase and chased with cold thymidine for either 4.5 min or 19.5 min are compared in Fig. 2*b* and *c*, respectively. After a short chase, karyomeres typically showed a trend towards more homogeneous labelling. While there is still a large percentage of grains present at the periphery, there appears to be a significant increase in central label. This trend in apparent relocalisation of grains is much clearer in Fig. 2*c* which shows that after a long chase period the DNA

labelled during a short pulse in early S is located predominantly in the central region of the nucleus and does not maintain a stable location at the periphery. Taken together, these results support the second possibility presented above: once replication is completed, the nascent DNA is displaced away from a stable site of replication located at the nuclear membrane.

We attempted to quantify our results using a histogram analysis (defined in legend of Fig. 3) as used by Huberman *et al.*¹². Figure 3 compares histograms derived from embryos labelled for pulse, long term, and pulse-chase periods. All the embryos labelled for short periods have central activities of less than 1.0 (Fig. 3*a*). The mean central activity in these embryos is 0.4 indicating that the peripheral areas are enriched with many more grains than would be expected if the nascent DNA were labelled homogeneously in all areas of the karyomere. In contrast, Fig. 3*b* shows that the majority of nuclei labelled continuously through the complete S-phase have central activities greater than 1.0 indicating a general lack of peripheral label. This result also indicates that most of the DNA is located in the central region of the nucleus. When embryos are pulsed

Fig. 3 Distribution of grains in nuclei of sea urchin embryos after various labelling conditions. Histogram analysis of central activities in cells labelled as in Fig. 2 for: *a*, pulse (30–100 s); *b*, continuously labelled (20 min); *c*, pulse/chase (labelled 30 s then chased for 4.5 min). Central activity is defined as the ratio of the fraction of grains which are central to the fraction of area which is central. A central activity of 1.0 indicates a homogeneous distribution of grains throughout the nucleus; ratios of < 1.0 signify a preferential labelling of the peripheral area. A central activity of > 1.0 indicates a preferential localisation of grains away from the periphery. Only karyomeres/nuclei with four or more grains were scored. Grains outside the nuclear membrane, regardless of their proximity, were not counted. For karyomeres, a rim 0.5 μ m in width was considered as the peripheral area. For nuclei, the peripheral area was a rim 1.5 μ m in width. This differentiation in width was made so that the percentage of area considered central in all cases remained approximately the same. To determine the ratio of area, paper tracings of the micrographs were made, the peripheral area measured and cut, and the fraction determined by the weight of the paper. The paper rim was then placed on the micrograph to determine the fraction of grains that were central. After the 4.5 min chase in (*c*) many grains are associated with the periphery probably because the large internal nucleotide pools¹⁶ are not completely diluted during such a short chase.

Fig. 4 Histogram analysis of grain distribution in late S phase labelled nuclei. *a*, Nuclei labelled for 30 s. *b*, Nuclei labelled for 90 s. Embryos developing at 16 °C were labelled beginning at both 108 and 112 min after fertilisation. After radioactive precursor incubation, samples were removed, fixed, and prepared for autoradiography as described in Fig. 1. Results from the short and long term labelling at both the 108 and 112 min time points were virtually the same and were combined.

and then chased for a short period the values for the central activities are shifted toward 1.0 (Fig. 3c), a trend away from the strong peripheral labelling and towards a more homogeneous labelling pattern.

Finally, we tested whether nascent DNA synthesised in the late S-phase is also localised in the peripheral region (Fig. 4). Embryos at 110 min after fertilisation were pulsed for 30 or 60 s. The S-phase in these embryos is at least two-thirds completed and the nuclei are entirely reformed. At this time the incorporation of exogenous precursor seems to occur much more slowly, based on the number of grains detected per nucleus in comparison to embryos in the early S-phase. But, like the patterns in early S-phase, the distribution of grains in nuclei pulse-labelled during late S indicates that incorporation is still taking place largely at the periphery (Fig. 4a). When these embryos are allowed to incorporate label for longer periods the central activity values are distributed around 1.0 (Fig. 4b) indicating a shift of grains away from the membrane.

The autoradiographic evidence presented here supports our previous biochemical studies indicating that the nuclear membrane may be involved with the temporal regulation of DNA replication in the sea urchin¹⁴. An enrichment of radioactive DNA in a presumptive DNA-membrane fraction was also found when we examined pulse-labelled nuclei of cultured mouse fibroblasts (3T3 cells)¹⁷; however an autoradiographic study in this system has not been reported. It is difficult to resolve our results with the autoradiographic results of others using mammalian culture cells. A possible explanation may be that autoradiographic analysis cannot distinguish between replication and repair synthesis of DNA, two activities known to occur in the S-phase nucleus. In the naturally synchronous sea urchin embryo where, during the S phase 1.8 pg of DNA is replicated in 12–15 min (ref. 15) semi-conservative replication may be assumed to be the principal synthetic activity. In mammalian culture cells, the period of time during which DNA is replicated is relatively long and it is now thought that replication events are initiated sporadically during this time¹⁸. This suggests that replication is not a continuous event during the DNA synthetic period and may be characterised by many starts and stops^{19,20}. Thus, a pulse label of cells from either

synchronised or unsynchronised cultures may result in the incorporation of exogenous precursor due to both repair and replication. Such a situation would confuse the interpretation of autoradiographs in determining subnuclear sites of replication.

In mammalian systems there is general agreement that during the late stage of the S-phase DNA synthesis occurs preferentially near the membrane^{9,11,12}. This result is commonly considered to be due to the replication of heterochromatin which is known to be replicated late in the S-phase^{21,22} and to be located near the membrane^{11,12,23}. In our studies the pulse-labelled DNA is preferentially located at the membrane both in the early and late S-phase. Furthermore it is clear that in this system virtually all of the DNA is located in the central region of the nucleus (Figs 2a, 3b). The simplest conclusion is that DNA synthesis occurs at the nuclear membrane and is relocated away from the membrane.

Primary structure of porcine relaxin: homology with insulin and related growth factors

HISAW and co-workers^{1,2} first described a factor from sow corpora lutea that caused relaxation of the pubic symphysis in oestrogen-primed guinea pigs. Subsequent studies have shown that the active substance, termed relaxin, is a low molecular weight peptide hormone. Its presence has been demonstrated during pregnancy in female pigs, guinea pigs, rabbits, mice and rats^{3,4}, and, more recently, in humans⁵. Its actions include dilatation and softening of the cervix, inhibition of uterine contractions and relaxation of the pubic symphysis and other pelvic joints. Relaxin, which has a molecular weight of approximately 6,000, consists of two non-identical chains joined by disulphide bridges⁶. We have now determined, and report here, the complete amino acid sequence of porcine relaxin.

Relaxin was purified from pregnant sow ovaries⁶; biological activity was localised by the mouse pubic symphysis bioassay⁷. Relaxin fractions used for structural studies had biopotencies in the range 1,100–1,500 guinea pig units (GPU) per mg relative to reference preparation NIH-R-P1 (potency 442 GPU mg⁻¹).

As a preliminary to sequence analysis, relaxin was reduced with dithioerythritol in urea or guanidine solutions

and alkylated with ^{14}C iodoacetic acid⁸. A number of methods were investigated for chain separation. During attempts to use ion exchange chromatography for this purpose it was observed that the longer chain (30 amino acids, designated 'B') was insoluble in the pH range 4-7, whereas the shorter chain (22 amino acids, designated 'A') remained soluble. Thus chain separation could be achieved simply by low speed centrifugation of the reduced carboxymethylated preparation. Schwabe *et al.* have described a similar procedure⁹.

The amino acid sequence of the A chain (Fig. 1) was established in three separate experiments by manual Edman degradation¹⁰. After 21 cycles the residual sample was subjected to amino acid analysis. Free carboxymethylcysteine was identified; thus this residue occupies the C terminal position in the A chain.

Sequence analysis of the B chain proved more difficult since the N terminus was found to be resistant to Edman degradation. Removal of the N-terminal blocking group could be achieved, however, by a pyrrolidone carboxylate peptidase¹¹. Thus the terminal residue was identified as pyroglutamic acid. Edman degradation was then carried out for 16 cycles on the deblocked B chain.

The remainder of the sequence (Fig. 1) was established by manual Edman degradation of the peptide Leu¹⁷ . . . Arg³⁰ isolated from a tryptic digest of carboxymethylated B chain. Confirmatory studies were carried out through Edman degradation and carboxypeptidase digestion of tryptic peptides isolated by preparative paper electrophoresis. Schwabe *et al.*⁹ have previously proposed a sequence for the A chain of relaxin identical to ours except that they find residue 10 to be glutamic acid whereas in three different preparations we clearly identified glutamine at this position. Deamidation of their material during isolation or sequence analysis could explain this discrepancy.

There are several features of the relaxin structure that deserve comment. The marked structural similarity to insulin is evident. Thus, relaxin consists of two dissimilar peptide chains of 22 and 30 residues respectively. The number and distribution of half-cystine residues are identical in the two hormones. Neither has free sulphhydryl groups. We have not yet rigorously established the pairing of the three disulphide bonds in relaxin; however, preliminary evidence suggests that the arrangement is identical to that of insulin, with two interchain bridges and an intra-

chain bridge in the relaxin. A chain linking the half-cystines at positions 8 and 13.

Amino acid sequence homology between relaxin and insulin is more obvious in the B than in the A chains (Figs 2 and 3). Superficially the A chain sequence homology does not seem impressive apart from the exact alignment of the four half-cystine residues. But, reference to the three-dimensional structure of insulin known from X-ray crystallographic studies^{12,13} shows that there is virtually complete conservation of the residues in the insulin A chain that contribute to the hydrophobic core of the molecule. These are the half-cystine residues found in insulin at A6 and A11, together with the A2 isoleucine (leucine in relaxin) and A16 leucine (isoleucine in relaxin). Two further residues from the insulin B chain (B11 and B15 leucines) complete the hydrophobic core; both are conserved in relaxin. A further perspective appears when residues invariant in all known insulin structures¹³ are examined. These (designated with asterisks in Figs 2 and 3) comprise 10 residues in each chain. At these 20 positions, a total of 15 residues are either identical or conservatively substituted in relaxin. Within the central helical region of the insulin B chain (B9 to 19) four of the five invariant residues are identical in relaxin; the fifth (tyrosine B16) is replaced by tryptophan in relaxin. At several other positions within this sequence substitutions are seen which conserve the hydrophilic or hydrophobic nature of the residue (for example, serine B9 is replaced by arginine in relaxin; glutamic acid B13 by arginine; leucine B17 by valine; valine B18 by isoleucine). These findings suggest that important elements of the tertiary structure of insulin are also present in relaxin, and that their overall three-dimensional structures may be quite similar.

An important difference is seen in the B chain where the zinc-binding histidine residue found at position B10 in almost all insulins is replaced by glutamic acid in relaxin. This makes it most probable that relaxin will not bind zinc and thus will not be able to form zinc-coordinated dimers or hexamers. In this relaxin resembles guinea pig, coypu and hagfish insulins, which are stable as monomers in solution even at high concentrations.

Relaxin has arginyl residues at the N terminus of the A chain (A1) and the C terminus of the B chain (B30). This arrangement, taken with the other evidence for homology, strongly suggests that relaxin is derived from a proinsulin-like biosynthetic precursor by proteolytic cleav-

Fig. 2 Comparison of sequences of insulin and relaxin A chains. Identical residues are enclosed in rectangles. Residues related through favoured substitutions²² are enclosed in circles. Residues invariant in all known insulin structures¹³ are indicated by asterisks.

age of a peptide connecting B30 to A1. Some earlier studies on relaxin also support the existence of a prohormone^{14,15}. In confirmation of earlier findings⁶ we have identified in ovarian extracts several forms of biologically active relaxin that differ slightly in net charge and amino acid composition from the peptide shown in Fig. 1. Chemical characterisation of these variants is still in progress; they could represent intermediates in the conversion of prohormone to hormone analogous to those described for insulin^{16,17} or degradation products.

The evolutionary relationship between relaxin and insulin is of considerable interest. It is likely that relaxin is related to insulin through a common ancestral polypeptide resembling proinsulin. Rinderknecht and Humbel¹⁸ have recently demonstrated a sequence homology between the insulin B chain and two polypeptides with non-suppressible insulin-like activities (NSILA I and II). These peptides are also clearly structurally related to relaxin (Fig. 3).

These homologies provide a basis for categorising relaxin as a member of a family of insulin-like growth factors with both structural and functional similarities in modulating cell growth and activity. These include nerve growth factor¹⁹, somatomedins A and C²⁰, and multiplication-stimulating factor²¹, as well as insulin and non-suppressible insulin-like activity (NSILA). Further structural studies should delineate the precise evolutionary relationships between these molecules.

We thank Mr McLaughlin (Farmer John Packing Company, Los Angeles) for assistance in the collection of pig ovaries; Dr F. J. Morgan for helpful discussions, and Dr Russell F. Doolittle for a gift of pyrrolidone carboxyl peptide. The work was supported by the US NIH and the National Health and MRC of Australia. Simon Kwok was a Fellow of the Hawaii Division, American Cancer Society.

Note added in proof: Our collaborators on the X-ray crystallography of relaxin (Drs Neil Isaacs and Guy Dodson of the University of York) have been able to fit the residues between the disulphide bridges of both chains of relaxin (A8-A22 and B10-B22) into the two-zinc insulin structure without producing significant distortion. Schwabe *et al.*²³ have proposed a sequence for the relaxin B chain that differs slightly from our own at the C terminus. Whether this discrepancy is due to technical problems or to the known C terminal heterogeneity of relaxin (see text) is unclear at present.

In vivo photoinactivation of *Escherichia coli* ribonucleotide reductase by near-ultraviolet light

NEAR-ULTRAVIOLET light (320-400 nm) is lethal to bacteria¹, yeast cells² and mammalian cells³. A large body of evidence correlates cell death and survival with the induction and repair of pyrimidine dimers in the DNA of cells irradiated by far-ultraviolet light (200-300 nm) (refs 4-7). The induction of pyrimidine dimers has also been demonstrated by 365-nm near-ultraviolet light but at 7×10^5 -fold lower efficiency than by 254-nm far-ultraviolet light⁸. With the exception of certain *Escherichia coli* strains with multiple deficiencies in DNA repair^{9,10} the small number of pyrimidine dimers produced by 365-nm near-ultraviolet light does not account for a significant fraction of the biological damage either in terms of lethality¹¹ or the inactivation of transforming DNA¹². The killing of cells by near-ultraviolet light is oxygen dependent whereas that by far-ultraviolet light is oxygen independent^{3,13}. The operational distinction between far- and near-ultraviolet light based on oxygen dependence of lethality coincides with the upper limit of ultraviolet light absorption by the

Table 1 Effect of near-ultraviolet irradiation on the activity of RDP-reductase, β -galactosidase and malate dehydrogenase

Dose (erg mm ⁻² $\times 10^{-4}$)	Activity remaining (%)		
	RDP- reductase	β - galactosidase	Malate dehydrogenase
0	100	100	100
3.0	35.4	—	—
7.5	24.7	—	—
15	3.5	99.5	97.6

E. coli TAU-bar was grown in glucose salts medium¹⁹. Mid exponential phase cultures were resuspended in 0.8% saline supplemented with 0.5 g l⁻¹ KCl and 0.4 g l⁻¹ CaCl₂ at 1.0×10^{10} cells per ml. Saline suspensions were irradiated at a dose rate of 3.0×10^3 erg min⁻¹ mm⁻² for 10, 25 and 50 min with aeration at 37 °C or were aerated at 37 °C without irradiation. RDP-reductase was assayed by the method of Warner²⁰ in whole cells made permeable to nucleotides by ether treatment. β -galactosidase and NAD-dependent malate dehydrogenase were assayed by standard spectrophotometric methods. Enzyme activities are expressed as a percentage of the unirradiated controls.

DNA at about 310 nm¹⁴ and may reflect the involvement of a primary target site other than DNA in the killing of cells by near-ultraviolet light. In *E. coli* deoxyribonucleotides are formed *de novo* by the reduction of ribonucleoside diphosphates¹⁵. Two of the components of the ribonucleoside diphosphate reductase (RDP-reductase) complex, the non-haem iron protein subunit of the RDP-reductase¹⁶ and the functionally linked flavoprotein thioredoxin reductase¹⁷ have strong absorption in the near-ultraviolet region. I show here that near-ultraviolet irradiation of *E. coli* cells selectively destroys RDP-reductase activity *in vivo* and present evidence relating the loss of RDP-reductase to the loss of cellular viability and to the inability of irradiated cells to support the replication of DNA phages.

Activity of RDP-reductase was measured in *E. coli*

Fig. 1 Percentage survival of colony forming ability as a function of near-ultraviolet dose in unsupplemented medium ($\square$), medium supplemented with deoxyadenosine ($\bullet$) or adenosine (Δ). Exponential phase cultures of *E. coli* TAU-bar were diluted to 5×10^7 cells per ml in glucose salts medium and were irradiated at 20 °C with aeration at a dose rate of 3.0×10^3 erg min⁻¹ mm⁻². In parallel experiments the medium was supplemented with deoxyadenosine or adenosine at 250 μ g ml⁻¹. All media contained thymine at 2.0 μ g ml⁻¹. Colony forming ability of irradiated cells was determined on L-agar. Irradiated glucose salts medium had no phototoxic effect when incubated with unirradiated cells.

Fig. 2 Percentage of survival of colony-forming ability ($\bullet$) and plaque-forming ability ($\square$) of *E. coli* Hfr H as a function of near-ultraviolet dose with *a*, T₇ phage and *b*, MS-2 phage. Irradiation conditions were as for Table 1. Irradiated cells were infected with T₇ or MS-2 phage at a multiplicity of 0.001. After 8 min adsorption at 37 °C the number of infectious centres was determined by plating with 5×10^6 unirradiated indicator bacteria on L-agar supplemented with 0.1 g l⁻¹ MgSO₄ and 0.2 g l⁻¹ CaCl₂. The total number of plaques was corrected for the number of chloroform resistant unadsorbed phage. In parallel experiments the colony forming ability of identically irradiated but uninfected cells was determined on L-agar.

TAU-bar as a function of the near-ultraviolet dose. Philips HPW 125 W black-light lamps (maximum emission at 365 nm) were used as the near-ultraviolet source. The irradiation apparatus² and the spectral characteristics of the light source¹⁸ have been described previously. Table 1 shows that about two-thirds of the RDP-reductase activity was destroyed by a dose of 3.0×10^4 erg mm⁻² and that there was nearly complete loss of RDP-reductase activity with a dose of 1.5×10^5 erg mm⁻². The activities of β -galactosidase and malate dehydrogenase were not significantly affected in this dose range indicating that the photo-destruction of RDP-reductase activity by near-ultraviolet was a specific effect.

Deoxythymidylate may be synthesised by two independent routes in *E. coli*, either by the *de novo* pathway involving RDP-reductase and thymidylate synthetase or by the salvage pathway utilising thymine and a deoxyribosyl donor²¹. When deprived of thymine, strains lacking thymidylate synthetase undergo lethal unbalanced growth termed thymineless death²². If the photoinactivation of RDP-reductase results in a metabolic state analogous to that occurring in thymineless death, it should be possible to abolish or diminish the lethal effect of near-ultraviolet light by providing the culture with an exogenous deoxyribosyl source. This prediction was tested using *E. coli* TAU-bar, a strain which in addition to lacking thymidylate synthetase is also deficient in deoxyriboaldolase²³. The second mutation results in efficient deoxythymidylate synthesis via the salvage pathway by blocking deoxyribose catabolism^{23,24}. Figure 1 shows the survival curves of *E. coli* TAU-bar irradiated in unsupplemented medium, in medium supplemented with 250 μ g ml⁻¹ deoxyadenosine or 250 μ g ml⁻¹ adenosine. With an initial dose of 4.5×10^4 erg mm⁻² rapid loss of viability occurred and was followed by a slower rate of killing with additional irradiation in unsupplemented medium. The inclusion of deoxyadenosine in the medium prevented the killing of cells up to a dose of 9.0×10^4 erg mm⁻². The survival pattern was similar in the medium supplemented with adenosine as in the unsupplemented medium indicating that the sparing effect was specific for the deoxyribosyl moiety. A reduction of the lethal effect of near-ultraviolet light also occurred with the prototrophic strain *E. coli* B/r thy⁺. After a dose of 4.5×10^4 erg mm⁻² survival was 0.020% in the unsupplemented medium, 0.20% in the medium supplemented with 250 μ g ml⁻¹ deoxyadenosine and 4.2% in the medium supplemented with both 250 μ g ml⁻¹ deoxyadenosine and 20 μ g ml⁻¹ thymine (survival curves not shown).

Another property of cells irradiated by near-ultraviolet light is the loss of their ability to support the replication of DNA phages^{25,26}. *E. coli* cells regain the ability to support the replication of T₁ DNA phage after low doses of near-ultraviolet irradiation when incubated in broth before infection suggesting that a metabolic lesion is involved²⁵. If this lesion is the loss of the RDP-reductase, and if other requisite host functions remain sufficiently intact to produce infectious phage, then it would be expected that the replication of RNA phages would not be suppressed by near-ultraviolet irradiation of the host. This prediction was tested using *E. coli* K-12 Hfr H as the host strain and the DNA phage T₇ and the RNA phage MS-2. Since the replication of the MS-2 genome is carried out by a phage specific RNA-dependent RNA polymerase²⁷ there is no requirement for deoxyribonucleotides. The capacity of irradiated cells to support the replication of T₇ phage was lost exponentially while there was a relatively small decline in the cellular viability up to a dose of 4.8×10^4 erg mm⁻². In contrast, cells which had received doses up to 3.0×10^5 erg mm⁻² retained their ability to support the replication of MS-2 phage while cellular viability was reduced to 0.00025% (Fig. 2).

The data presented here are consistent with the interpre-

tation that the underlying event in the killing of exponentially growing *E. coli* cells by near-ultraviolet light, and in the loss of the ability of irradiated host cells to support the replication of DNA phages, is the photoinactivation of the RDP-reductase complex.

Leader sequence of 71 nucleotides devoid of G in tobacco mosaic virus RNA

EXHAUSTIVE T₁ ribonuclease digestion of the RNA of tobacco mosaic virus (TMV) liberates an unusually large T₁ oligonucleotide (~72 nucleotides) called Ω (refs 1-4). Analysis of partial T₁ ribonuclease digestion products of uniformly ³²P-labelled TMV RNA shows that Ω is no more than 200 nucleotides from the 5'-end of the chain. We have used polynucleotide kinase to fix a radioactive phosphate to the 5'-end of both Ω and intact TMV RNA (after removal of the pppm⁷G 'cap') and determined the sequence of the first 15-16 nucleotides at the 5' terminus of each by two-dimensional homochromatography of partial P₁ nuclease digests. The results show that Ω begins only one nucleotide away from the 5'-end of the RNA chain, the terminal sequence being m⁷GpppG Ω . . . Consequently, positions 2-72 of the TMV RNA molecule are devoid of G (guanosine residues).

An early attempt to locate Ω in the RNA chain was founded upon the erroneous belief that mild sodium dodecyl sulphate treatment of TMV removes subunits preferentially from the end of the particle containing the 3' OH of the RNA chain⁵. Mandeles¹ found that Ω was exposed early in the course of such treatment, leading him to conclude that the oligonucleotide was within about 200 nucleotides of the 3' OH end. Recently, however, it has been established that the polarity of sodium dodecyl sulphate uncoating is the opposite of what was previously supposed^{6,7}, implying that Ω is near the 5' rather than the 3' end of the RNA molecule.

As noted above, TMV RNA begins with the sequence m⁷G⁺ ppp⁺G . . . (refs 8,9). The triphosphate bridge which joins the m⁷G cap to the 5' end of the RNA chain proper is resistant to endonucleolytic cleavage, and the RNase-resistant moiety, m⁷GpppGp, can be easily separated from the other products of digestion by ionophoresis at pH 3.5⁸. We have taken advantage of this property to screen a partial T₁ RNase digest of uniformly ³²P-labelled TMV

RNA for fragments coming from the 5'-end. When the partial digest was fractionated on a polyacrylamide gel, seven bands contained significant amounts of the fragments sought (Fig. 1a). Fragments 1-3 were successfully freed of contaminating material by an additional step of gel electrophoresis; fragments 4-7, however, have not yet been purified sufficiently to warrant sequence analysis.

The T1 RNase fingerprint of purified fragment 2 (240 nucleotides) is shown in Fig. 2. The cap structure, m⁷GpppGp, migrates as a diffuse spot to the right of UUG. The corresponding product in the pancreatic RNase fingerprint (not shown) was m⁷GpppGU.

As shown in Fig. 2, fragment 2 contains a large T1 oligonucleotide which we have identified as Ω , in line with the findings of Mandeles¹ (see above). Evidence that the indicated spot is indeed Ω includes the following: (1) treatment of the oligonucleotide with pancreatic RNase gives products in the ratio 4 AAU, 2AAAC, 3 AU, 6 AAC, 6 AC, approximately 13 U and 1-2 C to one G, in substantial agreement with the pancreatic RNase catalogue described for Ω by Garfin and Mandeles⁴; (2) the U₂ RNase catalogues are in reasonable accord except that we find U₅A rather than the U₆A reported by Garfin and Mandeles⁴ and probably U₄A instead of U₃A; and (3) the putative Ω has the same mobility in bidimensional gels as does authentic Ω from a T1 RNase digest of whole TMV RNA, Ω also forms

Fig. 1 Polyacrylamide gel electrophoresis of a partial T1 RNase digest of *a*, uniformly ³²P-labelled TMV RNA and *b*, 5'-³²P-labelled TMV RNA. Uniformly labelled TMV RNA was prepared as described by Guilley *et al.*¹⁷; 5'-terminal post-labelling of TMV RNA was carried out after chemical removal of m⁷G (ref. 10) and subsequent phosphatase treatment (0.02 units calf intestinal alkaline phosphatase per 100 μ g RNA; incubation for 30 min at 37°C). The buffer was 0.05 M Tris, 0.01 M MgCl₂, pH 7.5. The uncapped RNA (300 μ g in a final volume of 0.2 ml) was then incubated for 30 min at 37°C with 2 units polynucleotide kinase and 3 μ M γ -³²P-ATP (specific activity: 200 Ci mmol⁻¹). After each step of enzyme treatment in the above procedure the solution was extracted with phenol to inactivate the enzyme, and the integrity of the RNA was verified by electrophoresis in polyacrylamide-Agarose gels. Partial T1 RNase digestion was with 1 unit enzyme per 300 μ g RNA in 0.1 M Tris, 0.001 M EDTA, pH 7.5. After 30 min at 0°C the reaction was stopped by phenol extraction and the partial digest was electrophoresed through an 8% polyacrylamide gel¹⁷. Arrows mark the positions of the 5' terminal fragments referred to in the text; B marks the position of the bromophenol blue marker.

Fig. 2 T1 RNase fingerprint of 5'-terminal fragment 2 of TMV RNA. The first dimension was on a cellulose acetate strip at pH 3.5 and the second dimension on DEAE paper wetted with 7% formic acid.

part of fragment 3 (200 nucleotides) and fragment 1 (approximately 280 nucleotides).

A preliminary investigation of partial T1 RNase digestion products of purified fragment 2 suggested that Ω might lie very near the 5'-end of the sequence. This led us to determine the sequence of the first several nucleotides at the 5'-end of TMV RNA by partial P1 nuclease digestion of 5'-³²P-labelled fragments in the hope that this sequence might overlap that of Ω . But, before a radioactive phosphate can be attached at the 5'-terminus of TMV RNA, the blocking group must be removed. Towards this end, non-radioactive TMV RNA was treated with sodium periodate and with aniline to eliminate the m⁷G (refs 10,11) and the 5'-triphosphate group was removed with alkaline phosphatase. A radioactive phosphate was then fixed to the newly exposed 5' OH group by treatment with polynucleotide kinase prepared from T4-infected *E. coli*¹² in the presence of γ -³²P-ATP.

The 5'-³²P-TMV RNA was partially digested with T1 RNase and the mixture of fragments fractionated by polyacrylamide gel electrophoresis (Fig. 1b). As expected, the seven principal radioactive bands, each of which should represent a fragment from the 5'-end of the TMV RNA chain, correspond closely in mobility with the seven capped fragments detected by screening the partial digest of uniformly labelled RNA for m⁷GpppGp (see Fig. 1a).

The 5'-terminally labelled fragments shown in Fig. 1b were digested with the non-specific endonuclease P1 from *Penicillium citrinum* in mild conditions in order to generate a random population of 5'-labelled partial degradation products¹³. Figure 3a shows an autoradiogram of such a digest analysed by two dimensional homochromatography¹⁴. All seven fragments gave identical patterns. The first dimension of the fractionation was by electrophoresis at pH 3.5 (separation according to charge) and the second dimension by homochromatography (fractionation according to size). Within the limits of resolution in the second dimension, the

18–36 nucleotides. The fragment migrated in the gel with a mobility similar to that of the 30-nucleotide long 2S rRNA from *D. melanogaster*¹⁴.

To determine if the binding is sequence specific, the RNA fragment was eluted from the gel¹⁵ and RNase T1 and pancreatic RNase digests were subjected to fingerprint analysis¹⁶ (Fig. 2). Both fingerprints yielded simple patterns, the number of intense spots agreeing roughly with the expected size of the fragment. This suggested that the binding of IF3 was not random, but sequence specific, although the presence of more than one binding site could not be excluded.

The structures of the main oligonucleotides in the digests are shown in Fig. 3a. Four oligonucleotides in the pancreatic RNase digest correspond to four unique sequences in MS2 RNA (ref. 18), in positions 3,437–3,444 (GAAA-GAGC), 3,453–3,458 (GAAAGC), 3,473–3,479 (GAAA-GGU) and 3,496–3,501 (AGGGAC). This suggests that at least part of the binding site is located in the sequence 3,437–3,501 in the 3'-terminal untranslated region. The remainder of the pancreatic RNase fragments have no unique sequences and therefore cannot be located unam-

Fig. 1 Electrophoretic analysis of ³²P-MS2 RNA fragment remaining bound to IF3 after digestion with pancreatic RNase. ³²P-MS2 RNA (22.4 µg, prepared as described by Brownlee¹³) was incubated with IF3 (45 µg, prepared according to Lee-Huang *et al.*¹¹ to Step 4, 90% pure) in a total volume of 0.25 ml containing Tris-HCl, pH 7.8 (50 mM), NH₄Cl (50 mM), Mg(OAc)₂ (1 mM), GTP (1 mM) and β-mercaptoethanol (14 mM) for 12 min at 37°C. Pancreatic RNase (0.5 µg) was added and the incubation continued for a further 30 min at 37°C. A control incubation was carried out in the same way, but omitting the IF3. The incubations were worked up in one of two ways: (1) Direct phenol extractions (*a* and *b* (control)) of the reaction mixture and precipitation with ethanol. The precipitate was collected by centrifugation (30 min at 30,000 r.p.m.) and dried *in vacuo*. (2) Filtration through nitrocellulose (*c* and *d* (control)). The reaction mixture was cooled to 0°C and filtered slowly through nitrocellulose (Millipore, HAWP 02500, 0.45 µm). The filter was washed three times with 10-ml aliquots of buffer (Tris HCl, pH 7.8 (50 mM), NH₄Cl (50 mM) and Mg(OAc)₂ (1 mM)). RNA was extracted from the filter by shaking for 2 min at 70°C with 2 ml of 1:1 mixture of phenol and a buffer containing Tris-HCl, pH 7.8 (10 mM). The extract was cooled rapidly and the RNA precipitated with ethanol from the aqueous phase. A vertical slab gel (20 × 20 × 0.4 cm) containing 15% acrylamide and 0.375% bisacrylamide in a buffer containing Tris-HOAc, pH 8.2 (40 mM) and EDTA (1 mM) was prepared. The RNA samples were dissolved in 50 µl of this buffer containing 10% sucrose and bromophenol blue, applied to the gel and electrophoresed at 150 V for 16 h at 4°C. An autoradiograph of the gel was prepared. To prepare large quantities of the RNA fragment, the method described for slot *a* was used. In a typical experiment, 2 mg of ³²P-MS2 RNA was incubated with IF3 under conditions of maximal binding as determined by nitrocellulose filtration.

Fig. 2 Autoradiographs of fingerprints of *a*, RNase T1 and *b*, pancreatic RNase digests of the protected RNA. B indicates the position of the blue marker. The RNA fragment was prepared as described in Fig. 1, slot *a*. The band was eluted electrophoretically from the gel¹⁵ and fingerprints of RNase T1 and pancreatic RNase digests prepared¹⁶. The IF3 sample used in this preparation was 80% pure, as determined by SDS gel electrophoresis¹⁷. Fingerprints of RNase T1 and pancreatic RNase digests of the protected RNA prepared in exactly the same way, but using a homogeneous IF3 preparation differed only in the intensities of a few of the spots.

biguously. All except three (AGC, (AG,G)C and (AG,-AG,G)U), do however fit the sequence around the unique nucleotides mentioned. Of the RNase T1 digestion products, none is unique, but all except CCG, CCAG, AACG, UCUCG and (U₃C₃, AC, AU) correspond to the nucleotide sequence in the same region. The RNase T1 product U₃C₃-AC, AU) could not be unambiguously identified. It gives one spot on some fingerprints and two on others, but since it lacks a 3'-terminal G residue, it must represent the 3'-terminus of the protected region, which may account for its variability. The 3'-terminal untranslated sequence of MS2 RNA and the location of the digestion products within this region are shown in Fig. 3b. Thus, were the sequence continuous, its minimum length as determined by unique pancreatic RNase products would be 65 nucleotides, that is, twice the length determined by gel electrophoresis.

The pyrimidine-rich sequences 3,466–3,472 and 3,488–3,495 cannot be accounted for in the fingerprints. These regions may be less well protected against pancreatic RNase digestion and/or may suffer some breakdown during isolation of the fragment. But considering the small size of IF3, it seems more probable that these excisions indicate a binding site where different stretches of the RNA are held together in a specific secondary and tertiary structure. This may also account for the presence of the two pancreatic RNase and four RNase T1 products which originate from a more distant part of the MS2 RNA sequence. In this respect, the binding may be similar to the RNA-protein interactions observed between ribosomal RNA and ribosomal proteins where binding does not occur between continuous sequences in either of the participating molecules¹⁸.

So far as is known, the 3'-terminal untranslated region of mRNA has no role in the initiation process and the functional aspects of the binding of IF3 to this part of MS2 RNA remain open to speculation. It is interesting in this respect that S1 protein, which is supposed to participate in the same step as IF3 at the initiation of translation, binds near the 3'-terminus of QB RNA (ref. 10). IF3 may have

A histone-like protein from adenovirus chromatin

THE DNA in adenovirus is complexed with two viral specific polypeptides, VII and V, to form the compact core structure. There are 1,070 copies of VII (18,000 molecular weight) and 180 copies of V (45,000 MW) per viral genome of 36,000 base pairs¹. Corden *et al.*² have suggested that the combination of six copies of VII, one copy of V and 200 DNA base pairs form the basic subunit structure of adenovirus chromatin. Such arrangement is also characteristic of the eukaryotic chromatin subunit which is composed of eight histones (two each of H2a, H2b, H3 and H4) and a unit DNA length of approximately 200 base pairs (see ref. 3 for review). The major core protein, VII is highly basic; almost 23 mole per cent of the residues are arginine^{4–6}. A simple calculation reveals that the mass ratio of VII : DNA is 1 : 1 which is similar to the histone : DNA ratio in eukaryotic chromatin. This suggests that polypeptide VII–DNA interaction may be similar to that

Fig. 1 Quantitative sequencing at the N terminus of VII. The log of relative yield is plotted against the step number. Automatic Edman degradation was done in an Edman-Begg sequenator¹⁸ (Illitron). The programme for phenylisothiocyanate coupling, cyclisation and cleavage has been described¹⁹. In our first sequence attempt of VII, step 10 showed a 58% carryover of proline. In the second run, the programme was modified by repeating the coupling and cleavage reactions at step 9. This minor modification in the programme reduced the proline carryover to less than 20% at step 10. Quantitative identification at each step was performed by H1 hydrolysis of the thiazolinones and analysis of the parent amino acids on a Durrum D-500 analyser. The data was plotted according to Smithies *et al.*¹⁹ and corrected for background and carryover. &, Ala or Ser.

of histones and DNA. Amino acid sequence studies have revealed an asymmetric distribution of basic residues in the histones. In particular, the amino end is highly basic and is implicated in DNA binding; the carboxyl end is less basic yet more hydrophobic and is involved in histone-histone interactions^{7,8}. To determine if the amino end of VII is also basic, we isolated polypeptide VII from adenovirus type 2 in milligram yield⁹ and sequenced its amino end by automatic Edman degradation (Fig. 1). We present here a partial sequence determination.

Table I gives the composite sequence data of the N-terminal 40 residues from polypeptide VII. This data is confirmed by two independent quantitative sequence studies (Fig. 1). Our actual sequence data extends to residue 48; however, residues 41-48 have only been sequenced once and are therefore not reported here. It is apparent that the

first 27 residues are enriched in basic amino acids (12–27 are basic). This is in contrast to the adjacent non-basic region which extends from positions 28 to 48, in which there are only two arginine residues at positions 30 and 45.

Figure 2 shows a diagrammatic representation of the charged amino acids in the amino third of polypeptide VII. The asymmetric basic versus non-basic 'domains' as described above are clearly illustrated. In addition, two clusters of basic residues, a triplet of Lys 3-Lys-Arg 5 followed by a longer cluster of His 23-Lys-Arg-Gly-Arg 27 are observed. In between the clusters, His and Arg are segregated at near regular intervals; Arg 11, Arg 13, His 15, and Arg 17 are equidistant from each other while His 8 and Arg 11 are longer by one residue. These non-random distributions of basic amino acids have also been observed in histones^{8,9}, especially in H4, an arginine-rich histone. In H4 (1) about 45% of the first 20 residues are basic, (2) there is a cluster of five consecutive basic residues Lys 16-Arg-His-Arg-Lys 20, and (3) basic residues 3, 5, 8, 12 and 16, are almost equidistant from each other.

The similarity of cationic residue distributions in VII and a highly 'sequence-conserved' histone, H4, immediately raises the possibility that the basic region in VII may also serve as a DNA combining site. The fact that functionally related yet distinctive modifications do occur at the amino end of both DNA-combining basic proteins tends to support this view. As shown in Fig. 2, Ser 1 and Lys 5, 8, 12 and 16 of histone H4 may be modified by phosphorylation¹⁰ and acetylation¹¹. Sung and Dixon¹⁰ have suggested that phosphorylation as well as acetylation of these residues reduces the strong electrostatic binding to DNA at this region of the molecule. This may in turn facilitate the 'proper binding'¹² and assembly of histones into chromatin subunits¹³. It is known that polypeptide VII is synthesised as a precursor molecule P-VII (Pro VII⁹) which is packaged in immature virions^{14,15}. At the final stage of virus maturation, a specific endoprotease¹⁷ processes a 20-residue fragment from the amino end of the molecule⁹ to give rise to polypeptide VII. It is likely that this processing event may be related to adenovirus chromatin assembly. We have shown⁹ that this precursor fragment is hydrophobic and may also be acidic (amide status unknown). Thus, the presence of this precursor sequence in Pro-VII may serve to modulate the strong electrostatic binding of the basic 'domain' to DNA. The net result is analogous to that exerted by enzymic phosphorylation and acetylation of histone H4. Subsequent processing event of polypeptide VII enables this region to regain its binding capacity and, thus, allows assembly of adenovirus chromatin.

Fig. 2 Diagrammatic representation of the basic amino acid distribution at the NH₂ termini of adenovirus polypeptide VII and the arginine-rich histone H4. The 'basic domain' in the two proteins is illustrated. In histone H4 the possible sites of enzymatic phosphorylation (PO₄), acetylation (Ac) and methylation (Me) are shown. In polypeptide VII, a 20-residue precursor fragment exists at the amino end of the molecule before the final stages of viral assembly. Modifications seen in both systems may have similar roles in modulating the binding of the respective 'basic domain' to DNA.

Table 1 Summary of sequence data obtained from the N terminus of VII

A new theory of olfaction based on dispersion-induced optical activity

OPTICAL activity is physically induced in achiral solutes dissolved in chiral solvents and is measurable as dispersion-induced circular dichroism (DICD)^{1–3}. An intermolecular vibrational coupling mechanism of the induction⁴ has been analysed theoretically⁵ and is here proposed as the primary physical process in olfaction. This new theory of olfaction extends the well-known qualitative vibrational theory^{6–7}, to encompass both chiral^{8,9} and achiral odorous substances^{10,11}. A quantitative aspect of the new theory is supported by a strong correlation of the solvent-induced rotatory power of achiral ketones with their effectiveness as alarm pheromones for the ant species *Iridomyrmex pruinosus*¹¹.

The rotatory inducibilities⁴ of 26 aliphatic ketones were measured by circular dichroism and isotropic absorption spectroscopy in their $n-\pi^*$ transitions as the chiroptical anisotropy factors¹² $g = \Delta\epsilon/\epsilon$, where $\Delta\epsilon$ and ϵ are the dichroic and isotropic molar extinction coefficients respectively. The values of g obtained for solution in (–)-bornyl acetate (BAC) and in (S)-propylene carbonate (PC) (refs 2, 3) are shown in Fig. 1 together with the pheromone activities of the ketones reported by Blum *et al.*¹¹ from laboratory and field trials.

The g values for acetone (point 1) and the homologous normal methylalkyl ketones from C₅ to C₁₂ (3–10) gave line a by the method of averages, line b was similarly obtained for the 3-, and 4-alkanones lacking α -substituents (11, 13, 14, 16, 18), and line c from the point of intersection of a and b and the experimental points for the cyclic ketones (24–26). The bioassay values for the ketones presented a target or star pattern centred on the common point of intersection of a , b , and c at acetone (1) with the natural pheromone, 2-heptanone¹¹, (5), occurring near the centre of the pattern and with pheromone activity decreasing radially. The near coincidence of these two independent, symmetrical, data patterns is compelling evidence of a correlation between olfaction and induced optical activity.

The linear relationships of the g values are most readily explained in terms of helical molecular conformations imposed by vibrational coupling¹³ on the achiral ketones by the chiral solvent and olfactory receptor molecules and will be discussed elsewhere. Such helical structures are, of course, inherent in naturally chiral compounds.

It is evident that DICD and infrared spectrophotometry should provide a quantitative *in vitro* method for evaluating olfactory response to odorous substances and mimics of natural chemical signal compounds.

Fig. 1 Correlation of solvent-induced chiroptical anisotropy, g , of achiral ketones in (S)-propylene carbonate (PC) and (–)-bornyl acetate (BAC) with their bioassays as alarm pheromones of the ant *Iridomyrmex pruinosus* (Roger) taken from ref. 11. Pheromone activity increases with filling of the circles from empty at 0 to full at 4. A filled circle also designates the natural pheromone (5). $g = \Delta\epsilon/\epsilon$ was determined from CD and ultraviolet spectra run at $25.0 \pm 0.1^\circ\text{C}$ as described in refs 2 and 3. The ketones are: (1) to (10), the normal methylalkyl ketones from C₃ to C₁₂; (11) 3-pentanone; (12) 4-methyl-2-pentanone; (13) 3-heptanone; (14) 4-heptanone; (15) 5-methyl-2-hexanone; (16) 2-methyl-4-heptanone; (17) 5-nonanone; (18) 2,6-dimethyl-4-heptanone; (19) 3-methyl-2-butanone; (20) 3,3-dimethyl-2-butanone; (21) 5-hexen-2-one; (22) 2,4-dimethyl-3-pentanone; (23) 6-methyl-5-hepten-2-one; (24) cyclopropylmethyl ketone; (25) cyclodecanone; and (26) cyclododecanone.

I thank Dr R. H. Wright for bringing this problem to my attention, and the NRC of Canada for financial support.

Precise location of the crossover region in the λ attachment sequence

A PREREQUISITE for studying the DNA-protein interactions involved in integration and excision of λ is the determination of the DNA sequences of the attachment sites. Useful sequence data can only be obtained if the position of the attachment site is known precisely. To focus on this site

we have used genetically- and physically-defined deletions and substitutions ending in *att* as reference points whose position relative to the sites of action of restriction endonucleases can be determined. In this way we have located the middle of the attachment site to within ± 10 base pairs in a molecule 46,500 base pairs long¹.

The specialised transducing phages λ bio and λ gal carry the right and left prophage end attachment sites respectively, with an adjacent substitution of bacterial DNA and a deletion of part of the opposite end of the prophage (Fig. 1). On hybridisation with normal λ molecules, the heteroduplex molecules formed have a single-stranded region, one end of which corresponds to the junction of bacterial DNA and the attachment site (Fig. 1). One end of one of the double-stranded pieces of DNA that remain after complete digestion of the single-stranded region with the single-strand specific S1 nuclease^{2,3} thus corresponds to this junction. All the available evidence points to this junction being within the attachment sequence and not at the end of it⁸⁻¹³. Thus the region of non-homology in the heteroduplex molecules of λ gal and λ includes the recognition sequences P and B (refs 9, 10), and the region of non-homology in λ bio/ λ heteroduplex molecules includes P' and B' (Fig. 1).

We determined the distance from Bam HI site 3 (ref. 5) to the crossover region by hybridising¹⁴ λ imm⁴³⁴ and λ gal₈ DNA and digesting sequentially with S1 nuclease and Bam HI. In each of five experiments two small DNA pieces were

detected, one 1,000 base pairs long (probably Bam HI cut 4 to *imm*⁴³⁴, 2.3% λ , 1,070 base pairs), and one 260 base pairs long (Fig. 2a). As a standard for comparison, we used ϕ X174 RFI DNA Hha I fragments, the lengths of which are known from DNA sequencing work¹³. Digestion of λ *imm*⁴³⁴ or λ *gal*₈ DNA with Bam HI and S1 singly or in combination and digestion of the DNA in the hybridisation mix with either enzyme alone does not give rise to any DNA pieces in this size range. The smaller of the two

pieces can be further positively identified as containing DNA between Bam HI site 3 and *att*, since it can be further digested with Hinf to yield the fragment δ (see below), and a fragment that is 215–220 base pairs long (Fig. 2c). Digestion of λ or λ *pbio*₁ DNA with Hind III yields two DNA fragments in the size range 10–1,000 base pairs. One is 620 base pairs long (1.3% λ) and probably represents DNA between Hind III cuts 4 (76.4% λ) and 5 (77.4% λ) (refs 6, 7). The other is only 130 base pairs long,

Fig. 2 Autoradiographs of DNA fragments in polyacrylamide gels. *a1*, Phage λ *pgal*₈/ λ *imm*⁴³⁴ heteroduplexes treated with S1 and Bam HI; *b1*, phage λ / λ *pbio*₁ heteroduplexes treated with S1 and Hind III; *c1*, fragment *att*-Bam HI cut 3 treated with Hinf; *d2*, fragment α treated with Hinf; *e2*, fragment α end-labelled with ³²P treated with Hha I. Hybridisation was carried out according to Fanning *et al.*¹⁴. Incubation with S1 nuclease was in 0.03 M Na acetate, pH 4.6, 10⁻⁴ M ZnSO₄, 0.1 M NaCl for 30 min at 22 °C. The DNA was then ethanol precipitated, washed with ethanol, dried and taken up in the buffer for the restriction enzyme digestion. Restriction endonuclease digestion was carried out at 37 °C in the following conditions: Bam HI (purified according to Wilson and Young¹⁹) in 6 mM Tris, pH 7.4, 6 mM MgCl₂, 6 mM 2-mercaptoethanol, 30 mM NaCl, Hind III (Miles Laboratories and Biolabs Inc.) in 6 mM Tris, pH 7.4, 6 mM MgCl₂, 30 mM NaCl, Hha I (gift of E. Winnacker, and Biolabs Inc.) in 6 mM Tris, pH 7.4, 6 mM MgCl₂, 6 mM 2-mercaptoethanol, 50 mM NaCl, Hinf (gift of A. Waltz) in 10 mM Tris, pH 7.4, 15 mM MgCl₂, 0.6 mM DTT. It was sometimes necessary to separate large fragments from small products of S1 digestion in a 0–20% sucrose gradient run at 41,000 r.p.m. in a Beckman SW41 ti rotor for 14 h at 4 °C before treating with the restriction endonuclease. The source of α (Hind III cut 3-Bam HI cut 3) was pMG 1409, a derivative of pSF 2124 (ref. 17) carrying the EcoRI C (ref. 18) fragment. The hybrid plasmid was constructed by *in vitro* ligation of the λ EcoRI fragment¹⁸ with RSF 2124 (ref. 17) linearised by EcoRI. The λ EcoRI C fragment had been purified using 0.8% Agarose gels and KI equilibrium gradient centrifugation²⁵. The ligation mixture contained 70 μ g of plasmid DNA and 1.5 μ g of λ EcoRI C fragment, in a total volume of 1 ml of 50 mM Tris, pH 7.5, 50 mM NaCl, 35 mM MgCl₂, 5 mM DTT, 0.066 mM ATP, with 0.5 U of T4 DNA ligase (Miles). Cells were transformed using the CaCl₂ technique²⁶ and transformants were selected on plates containing ampicillin (100 μ g ml⁻¹). Clones containing the hybrid plasmid were identified by their resistance to ampicillin and their failure to produce colicin EI. Plasmid DNA was purified according to Clewell and Helinski¹⁹ with minor modifications. Digestion of this plasmid DNA with Hind III and Bam HI gives α and fragments ~7,000 and 8,300 base pairs long. α can be prepurified on a 0–20% sucrose gradient run for 18 h at 41,000 r.p.m. at 4 °C in the Beckman SW41 ti rotor. DNA fragments were labelled *in vitro* by nick translation²⁰ in 50 mM Tris, pH 7.4, 10 mM MgCl₂, 0.1 μ M 2-mercaptoethanol, 5–10 μ Ci of one α -³²P-labelled nucleotide triphosphate (dried to remove ethanol if necessary), the three other deoxynucleotide triphosphates 0.05 mM, with 1–2 units DNA polymerase I (Boehringer, Grade I) for 1 h at room temperature. The reaction was stopped by heating at 70 °C for 10 min. Nick translation usually followed digestion with the restriction enzyme. Fragments were end-labelled by treating with bacterial alkaline phosphatase (Worthington BAPF) for 1 h at 37 °C, extracting once with phenol and once with ether, precipitating and washing with ethanol, taking the dried precipitate up in 20 μ l of a solution containing 1 μ M γ -³²P-ATP (NEN), 50 mM Tris, pH 7.4, 10 mM MgCl₂, 5 mM DTT and 1 mM spermidine, and incubating with 0.5–3 units of polynucleotide kinase (Miles Laboratories, Biolabs Inc.) for 30 min at 37 °C. Samples were subjected to electrophoresis on 8% polyacrylamide slab gels (14 $\times$ 30 $\times$ 0.2 cm). The running buffer was 50 mM Tris borate, pH 8.3, 1 mM EDTA. After running the gel at 15 °C at 200 V for 14 h, the gel was autoradiographed. The numbers adjacent to the bands indicate the numbers of base pairs of the respective fragments.

so there must be a hitherto undetected Hind III cut very close to one of the others. A new band appears when λ and λ bio_I DNAs are hybridised and digested sequentially with S1 and Hind III (Fig. 2b). In three separate experiments, the length of this DNA piece was determined as 320 base pairs. This band is not seen when the DNA in the hybridisation mix is digested with either enzyme separately, and represents DNA between Hind III cut 3 and the left end of the bio_I substitution, since the right end of the bio_I substitution is 9.7% λ (4,500 base pairs) away from the next Hind III cut^{1,6,7}.

The sum of the lengths of the Bam HI₃-att and Hind III₃-att DNA pieces is 580 base pairs. To obtain an independent estimate of this distance, we isolated the Hind III₃-Bam HI₃ piece (Fig. 2), which we call α . α can be cut by the restriction endonuclease Hinf to yield three pieces, β , γ and δ (Fig. 2d). If the 5' ends of α are labelled using polynucleotide kinase and then digested with Hinf, only γ and δ are labelled (Fig. 2e). A fragment identical in mobility to δ is obtained by Hinf digestion of the Bam HI-att fragment (Fig. 2c). Thus δ is to the right, γ to the left, and β in the middle. The lengths of β , γ and δ as determined by ten separate measurements of their mobilities in gels are 360, 150 and 45 base pairs respectively, giving 555 base pairs for α . No other fragments have been detected, and the radioactivity present in the three bands after nick translation with α -³²P-dGTP is in the ratio 7.4:3.5:1, which is similar to the ratio of the fragment lengths, 8:3.3:1. Endonuclease Hha I also cuts α twice, yielding three fragments that are 470, 65 and 15 base pairs long, their sum being 550 base pairs. Mbo_{II} also cuts α twice yielding three fragments 380, 90 and 75 base pairs long, their sum being 545 base pairs. These values agree very well with the value obtained from the sizes of the Hinf fragments. We therefore have four independent measurements of the distance between Hind III cut 3 and Bam HI cut 3; 550, 555 and 545 from the Hha I, Hinf and Mbo_{II} pieces, 580 from the Hind III-S1 plus Bam HI-S1 pieces. The difference is too large to be accounted for by errors of measurement. No significant change in the observed size of the Bam HI₃-att piece was seen on increasing the amount of S1 nuclease twofold or decreasing it fivefold, so digestion of the single-stranded region with S1 was complete. One possibility is that a fragment or fragments have a mobility that does not correspond well to its

real length²¹. A more interesting possibility arises from the fact that if a common region of homology^{22,23} is present in the attachment sequences of phage and host, the ends left by S1 in the attachment region will be at the junction between the common homology region and a recognition sequence (Fig. 1). In this case the ends should overlap by the length of the common homology region, so the discrepancy in the values obtained would indicate a common homology region of 20–25 base pairs (Fig. 3).

The position of the site of recombination is shown in Fig. 3. It is thus possible in this way to determine the physical map position of genetically-defined elements in large DNA molecules to within 20 nucleotides.

Fig. 3 Map of the attachment site region of λ . The sizes of the Hinf fragments form the basis of the map. Digestion of the Hinf fragments individually with Hha I and Mbo_{II} places the Hha I cuts 15 and 80 base pairs from the Hind III cut, the Mbo_{II} cuts 90 base pairs from the Hind III cut and 75 base pairs from the Bam HI cut. Marini and Landy²⁴ have also found a 380 base-pairs long Mbo_{II} piece containing att. The restriction endonucleases Hpa I, Hpa II, Hae II, Hae III, Hind II, Hind III, Bam HI, Sac III and Pst I do not cut within this DNA segment. Filled arrow, solid tail: Hind III; unfilled arrow, Bam HI; filled arrow, dotted tail: Hinf. Lengths of the fragments are given in base pairs.

Function of byssus threads in young postlarval *Mytilus*

STUDY of the settlement of postlarvae of *Mytilus edulis*, which live attached to filiform algae and hydroids, has shown that they migrate frequently^{1,2}. They detach themselves from their byssus, leave the substratum, are transported again by the water and re-attach on a new substratum. Like Sigurdsson *et al.*¹, we observed long mucous threads on young mussels and compared the drifting at the end of a long thread with the gossamer flight of young spiders, but believed that the aberrant primary byssus thread⁴ was involved chiefly in the settlement of the young. We tested this assumption. We placed a tuft of the alga *Polysiphonia* with many attached mussels in a transparent annular tank (diameter 1 m) in which a constant rotating current was generated. Four small racks with 1.5 m of nylon thread wound around them were placed perpendicular to the current. After 1 d some of the mussels, usually some hundreds, had resettled from the alga on to the threads.

Of the young mussels carried along by the current, occasionally one remained at the spot 2–10 cm downstream a nylon thread, apparently connected by the byssus thread, which had trailed behind and made contact with the substratum. At this anchored stage the elastic mucous thread protruded from between the valves at a point near the apex. Then the animal made swinging movements around this point over an angle of 60°, and in doing so pulled in the byssus thread, again behaving like a spider. Frequently a mussel was able to reach the substratum in this way, but the connection could also be lost. It seemed to be especially difficult for the mussel to grip the substratum with its long motile foot. Sometimes the substratum was abandoned again after short inspection. In such cases time was needed to perform a new anchoring procedure, and this corresponded with the time needed to secrete a new thread.

When nylon threads with diameters in the range 120–1,000 μm were stretched on racks in the sea, the thicker threads caught significantly larger mussels ($P < 0.001$), but such a difference consistently found in the tank was never significant. The average length of the young mussels caught on nylon threads varied in different experi-

ments between 900 and 1,500 μm , the smallest measuring 240 μm (metamorphosis), the largest 2,000 μm or more.

The behaviour of the migrating postlarvae may explain the high resettlement rates found at sea—600 specimens in 5 d—per metre of nylon thread stretched perpendicular to the direction of the current in midwater. In the tank a current of 20 cm s^{-1} was most effective. In the sea the water movement in waves is possibly more important for settlement than are tidal currents.

Liquid immiscibility in $\text{K}_2\text{O}-\text{FeO}-\text{Al}_2\text{O}_3-\text{SiO}_2$

VISSE and Koster van Groos¹ present a new phase equilibrium diagram for the plane leucite-fayalite- SiO_2 in the quaternary system $\text{K}_2\text{O}-\text{FeO}-\text{Al}_2\text{O}_3-\text{SiO}_2$, in which the field of immiscibility differs significantly from that which I presented earlier², and from that presented by Greig on the binary $\text{FeO}-\text{SiO}_2$ (ref. 3) (Fig. 1). Here I suggest the reason for the discrepancy, as no discussion or explanation is given by Visser and Koster van Groos.

The few details presented on the laboratory procedures used in the new work¹ suffice to indicate that their results should differ somewhat from mine. First, the oxygen fugacity during their work was slightly higher, as they note, because they used molybdenum rather than iron containers. The resulting presence of more Fe^{3+} in the melts would almost certainly expand the field of immiscibility⁴. I am assuming that they were able to overcome the difficult problems of obtaining adequate transfer of oxygen through their evacuated system to achieve PO_2 buffering. Second, the use of a vacuum during the runs in their work might cause loss of

Fig. 1 Phase relations in the system $\text{K}_2\text{O}-\text{FeO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ (inset), showing two fields of stable immiscibility (shaded), projected on the plane leucite (Lc)-fayalite (Fa)- SiO_2 , plotted in wt. %, from the early work of Roedder³. The outline of the larger field of immiscibility newly reported by Visser and Koster van Groos¹ is also shown (dotted). Tr, tridymite; Cr, cristobalite; Kf, K-feldspar. The T-X section along the line F-H is based on early work of Roedder³, plus the work of Watson¹¹ (point P) and Irvine¹⁰ (point Q). Two immiscible liquids exist in stable equilibrium along D-P-C and G-H.

potassium which would also increase the degree of oxidation of the charges. Third, the molybdenum containers must have put some molybdenum into the charges, either as Mo^{4+} or Mo^{6+} , both of which might be expected to increase the field of immiscibility⁴. I do not believe, however, that these three effects, even though additive, are adequate to explain the major differences found in the extent of the field of immiscibility.

Neither the work of Visser and Koster van Groos, nor my work gives the compositions studied nor the temperatures of the individual runs, but the numbers involved—~500 runs on 26 compositions in my work and >150 runs on an unspecified number of compositions in theirs—would both seem adequate to delineate the phase boundaries. (Although my diagram was presented as “preliminary” at the time, it has since been corroborated by additional data⁵.)

The differences between the two studies can be explained perfectly, however, by the assumption that some of immiscibility found by Visser and Koster van Groos took place during quenching, as the melt passed down through a field of metastable subliquidus immiscibility. The existence of such a field under the liquidus surface for silica in the system as I depicted it is self-evident from the geometry of the two immiscibility fields in a T-X section from the FeO-SiO₂ sideline through points C and D on Fig. 1. Furthermore, experimental evidence has been found for the existence of this metastable field, as well as for a metastable extension out under the very flat fayalite liquidus⁷. This evidence consisted of the presence of minute (~1 µm) globules having a high index, presumably high-FeO melt, in those glasses formed on relatively slow quenching, whereas the same charge quenched more rapidly yielded an optically uniform glass. Unfortunately, neither paper provides details on the quenching procedures. In my work, I quenched by dropping the iron foil envelope (~1×5×5 mm) containing the charge on to mercury while still in pure nitrogen. If the results suggested that phase changes had taken place on quench (for example, the minute globules, or dendritic crystals), faster quench was obtained by attaching platinum weights to the charge in the furnace to cause it to sink in the mercury on dropping⁸. All such minute globules were eliminated by this procedure.

The metastable sub-liquidus immiscibility indicated on Fig. 1 was originally drawn solely on the basis of the thermodynamic necessity of metastable extensions of the experimentally determined stable equilibria. It has been verified experimentally by Irvine¹⁰, who determined the stable and metastable phase relations for composition Q (Fig. 1) at 1,350 °C. The stable assemblage consisted of tridymite crystals and a liquid. Irvine was able to realise metastable immiscibility in this composition, with exsolved globules as much as 7 µm diameter, by superheating to 1,550 °C for 1–2 h, then supercooling for 10–15 min before quenching. The metastable solvus was 'roughly bracketed at 1,350 °C', which agrees well with the extension sketched in Fig. 1. Additional corroboration of the phase relations as sketched in Fig. 1 comes from some runs by Watson¹¹, establishing the 1,180 °C isotherm on the upper surface on the stable immiscibility field. He found this isotherm to intersect the stable two-liquid field at point P on the section (Fig. 1).

Metastable sub-liquidus immiscibility is commonly observed in the field of ceramics, and an extensive literature

exists⁹. Visser and Koster van Groos have used a very sensitive test for such immiscibility (electron scanning microscopy on etched surfaces), and they may even have detected such metastable immiscibility in samples that would seem optically homogeneous. Such metastability would explain many of the features they describe that are otherwise extremely puzzling. (Thus the field of immiscibility as drawn by Visser and Koster van Groos indicates a precipitous drop of 517 °C in the liquidus for silica in the system FeO-SiO₂ by the addition of only 1.35% FeO, and the metastable subliquidus extension of the immiscibility field would have to be even steeper). In view of the above evidence, I cannot accept their diagram as representing stable equilibria. I would suggest that the 'submicroscopic' immiscibility reported by them probably is metastable immiscibility from too slow quenching, and that only their coarser globules (as much as to 3 mm) represent stable immiscibility at furnace temperature.

VISSER and Koster van Groos¹ have delineated a two-liquid phase field in the system K₂O-FeO-Al₂O₃-SiO₂ which is considerably larger than that reported by Roedder². Furthermore, the extent of the revised two-liquid region on the fayalite-silica join contradicts the phase equilibrium data for the system FeO-Fe₂O₃-SiO₂ (ref. 3). In our opinion the new data probably overestimate the extent of the stable liquid immiscibility field of this system for the following reasons.

(1) The submicroscopic glass-in-glass textures found in charges quenched from between 1,250 and 1,400 °C (ref. 1) are probably not equilibrium associations formed at the run temperature. They probably formed as the melt was quenched through a metastable immiscibility field below the liquidus surface. This explanation would account for the anomalous situation of certain conjugate liquid pairs forming

globules no larger than a few tenths of a micron, whereas macroscopic globules up to 3 mm in diameter form in charges differing only slightly in bulk composition¹. The textures figured¹ are identical in scale and morphology to those produced by quenching silicate melts through sub-liquidus immiscibility domes or by heat-treating supercooled silicate liquids^{4,5}.

(2) Previous studies⁶ show that minor amounts of molybdenum (up to 0.5 weight %) are dissolved by melts held in molybdenum capsules, where the oxygen fugacity is buffered at Fe-FeO by gas mixtures. The technique used by Visser and Koster van Groos¹ depends on the equilibration of melt and molybdenum sample container to buffer the oxygen fugacity of the charge, and is likely to be very favourable to the solution of Mo. Experiments in this laboratory show that the addition of 1 wt % molybdenum to the composition 40 fayalite, 26 leucite, 34 silica raises the upper limit of the two-liquid field by >30 °C. This exceeds the difference in temperature between the fayalite-tridymite cotectic and the leucite rich limit of the miscibility gap¹. Solution of molybdenum from the sample container⁶ would extend the stable two-liquid regions, as observed^{1–3}.

Using ⁸⁰Pt ²⁰Rh wire loop sample containers to minimise iron loss from the charge⁷ and controlled oxygen fugacity at the Fe-FeO buffer, we have confirmed the existence of a low temperature stable immiscibility field isolated from the fayalite-silica join, reported by Roedder². Glass beads formed using the wire loop technique have been analysed and show about a 10% loss of K₂O during an 18-h run; the effect of this loss on the geometry of the immiscible field is minor and where we have analysed the run products can be allowed for on the diagram. In conclusion, the statement that "at least for dry magmas an FeO-rich basalt must yield an immiscible granitic liquid during the later stage of crystallisation"¹ would seem to be premature.

VISSER AND KOSTER VAN GROOS REPLY—The data which suggested to us that the liquid immiscibility field was significantly larger¹ than previously determined² were based on two independent phenomena. Runs at high temperatures (1,550 and 1,735 °C), made in molybdenum capsules in an induction furnace, showed extensive development of two immiscible liquids for compositions containing up to 7 wt % $\text{Al}_2\text{O}_3 + \text{K}_2\text{O}$. Spheres up to 1 mm in diameter were formed. The P_{O_2} was bracketed between the Mo–MoO₂ buffer and the Fe–FeO buffer (Fig. 1), and is estimated at 10^{-8} . Because the low-temperature two-liquid field at about 1,250 °C was found with compositions containing 8 wt % $\text{Al}_2\text{O}_3 + \text{K}_2\text{O}$, we thought the two immiscibility fields to be continuous. Therefore we investigated the intermediate temperature range between 1,250 and 1,500 °C. In the runs at these temperatures we found only submicroscopic separation between two liquid phases. We interpreted these as a stable phenomena because quench was relatively fast (5–10 s). Development of submicroscopic separation textures was identical to those at lower temperatures where we found a continuous range from large spheres (2 mm) to submicroscopic textures (Fig. 2a (1)). This suggested some kinetic problem for the phase separation at these temperatures. On the basis of the above we suggested a revision of the liquidus in the system K_2O –FeO– Al_2O_3 – SiO_2 .

Our recent findings, however, indicate that the major criticism of Freestone and Hamilton³ and Roedder⁴ is substantially correct. Thus, a large part of the immiscibility field as depicted in

our paper¹ is metastable, the stable part is in good agreement with Roedder's data². Before elaborating on this, we shall make some remarks on our experimental procedure. Most of our earlier runs were made by wrapping 250-mg samples in molybdenum foil, and sealing under vacuum in quartz tubing. We selected this technique because the wire loop method will most likely result in serious K_2O losses. Bow *et al.*⁷ report 20% loss (open capsules); O'Hara *et al.*⁵ 15% loss (open capsules); Freestone and Hamilton³ 10% (wire loop); while Naslund (wire loop)⁶ considers the loss insignificant. It is very important to keep the $\text{K}_2\text{O} : \text{Al}_2\text{O}_3$ ratio close to 1, or at least at a constant value, because change in this ratio effects the phase relations and the extent of the immiscibility field.

Several high temperature runs were made in an induction furnace, using molybdenum capsules sealed in platinum capsules. In our current research

we use sealed molybdenum capsules in an argon atmosphere. The gas flow through the furnace is set at the Mo–MoO₂ buffer. While these capsules develop hairline cracks during the run, K_2O losses are minimal. Furthermore, quenching times are reduced to about 0.25 s from the previous 5–10 s. As shown in Fig. 1, the prevailing molybdenum buffer, is Mo–MoO₂, the partial pressure of MoO₃ still very low.

In the experiments, the FeO loss to the sample holder was found to be insignificant; furthermore, the MoO₂ content of the silicate glasses is less than 0.1 wt % (detection limit) in all runs except those made in the induction furnace. Here the MoO₂ content of the glasses was about 0.6 wt %.

With our current method we repeated the high-temperature (1,735°, 1,550 °C) runs. We were unable to reproduce our previous results showing immiscibility textures. Comparison with the previous analytical data show that the $\text{K}_2\text{O} : \text{Al}_2\text{O}_3$ ratio of the earlier runs was very low (0.1) as compared with the new data (0.6–1.1). The MoO₂ content of these glasses is below the detection limit. It seems therefore that the low $\text{K}_2\text{O} : \text{Al}_2\text{O}_3$ ratio, possibly combined with the high MoO₂ content, resulted in the formation of immiscible textures. Results of the larger scale separation were in excellent agreement with our earlier runs. The submicroscopic separation features, however, were not reproduced in most runs owing to a better quenching method.

The submicroscopic phase separation was investigated with an energy dispersion in combination with a scanning electron microscope. Tie-lines of the co-existing liquids are much longer than those determined from the microscopic scale phase separation in the same sample. The lengths of these tie-lines roughly delineate the immiscibility field, as it was shown earlier¹, supporting the revised interpretation that this extend of this field represents the metastable extension of the two immiscibility fields found previously².

This research was supported by the NSF (grant no. DES 74-14745).

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

Fig. 1 Systems Fe–O and Mo–O. The heavy line depicts the stability relations of the Fe–O system. The lightly drawn lines depict reactions in the system Mo–O which are independent of the MoO₃ and (MoO₃)₂ vapour pressures, while the dashed lines depend on the (MoO₃)₂ pressure and the dot-dashed lines on the MoO₃ pressure. Runs were made in shaded areas. A, Mo (metal); B, MoO₂; C, MoO₃ (liquid); D, MoO₃ (vapour); E, (MoO₃)₂ (vapour). Data from ref. 7.

reviews

Popularising chemistry

A. R. Todd

New Worlds in Chemistry. By Martin Sherwood. Pp. 234 (Faber and Faber London, 1977.) £6.95

WITHOUT CHEMISTRY and the great industries based upon it, material civilisation as we know it has no future. The enormous changes which have taken place in the pattern of our daily lives during the past century or so have depended almost entirely on the progress of chemistry—the most central of the sciences whose tentacles reach out through all the others. Without it, the translation of most of the discoveries made in other sciences into practical, usable forms would simply not have occurred; and what is true of the past will be equally true in the future. Despite this, chemistry is undoubtedly less well known and well regarded than, for example, physics or biology by the general public, and it is rarely the subject of popular presentations on radio, television, or in the press. There is no single reason for this state of affairs, but from the many that could be adduced I would choose two as being of major importance.

The first is that the very ubiquity of chemistry and its products makes it a generally accepted part of everyday life to be noticed only when something untoward occurs, whereupon the public reacts with a display of frequently unfounded fear or panic. People, in other words, are aware of chemistry only dimly through its products or applications and are, for the most part, ignorant of or indifferent to the science itself.

The second is that chemistry, however absorbing it may be to its adherents, is inherently difficult to 'popularise'. To be understood, it requires acceptance of certain abstract concepts such as valency, bonding, and three-dimensional orientation of valencies, which have no real counterpart in everyday life. As a result the 'man-in-the-street' is usually unable to appreciate the chemist's ideas of molecular structure and interactions. This inability is not in my view simply due to chemical jargon. Be that as it may, popular expositions of the science have been few in number and successful ones even fewer. The appearance of *New Worlds in Chemistry* is therefore of more than passing interest.

In his new book, Dr Sherwood has done an excellent job of putting across a picture of modern chemistry in action. I found it extremely readable—journalistic here and there, perhaps, but probably none the worse for that. It seems to me that he has been successful because, accepting the ubiquity and maturity of the science, he devotes most

of his attention not to the search for spectacular events but to emphasising and exemplifying the part chemistry has played in a number of important developments in industry, in biology and in medicine, and in efforts to understand the origin of life on our planet.

The book opens with two chapters (47 pages in all) on the "Elements" and "Mechanics" of chemistry. Together they form a praiseworthy attempt to give a comprehensible yet reasonably accurate picture of the basis of chemistry today. I found it both readable and informative, but I was left wondering whether the general reader with no previous knowledge of chemistry would not still be in something of a fog after reading it.

The chapter on "Chemistry in the Beginning" gives a very—and perhaps unduly—full account of work on and theories relating to the development of organic compounds of varying complexity under pre-biotic conditions. Opinions vary about the value of much of the work on pre-biotic synthesis, since it is hardly surprising that organic compounds could be produced in conditions which would not support life as we know it. What would be far more

interesting would be the beginning of organisation—the appearance of coupled reactions under close control which is surely the real beginning of life; but of that we still know little.

The sections on the chemistry of life and death, on industrial chemistry and on the significance of chemistry in a variety of human activities from agriculture to fine art are well done, and the book closes with a chapter on "Chemistry and Tomorrow." In this chapter Dr Sherwood is brief and cautious in forecasting likely areas of advance but he devotes a good deal of space to the well worn question of the relationship between science and government, and the social responsibility of the scientist. These subjects are, of course, controversial but the author is right to point out the dangers inherent in the growing public awareness of the large scale effects which can be produced by modern technology and the need to prevent disillusion with science by the provision of adequate information. Taken as a whole *New Worlds in Chemistry* is a contribution to this end and it can be recommended to the general reader. □

Lord Todd is President of the Royal Society and Master of Christ's College, Cambridge.

Vibrations of crystals

Vibration Spectra and Symmetry of Crystals. By H. Poulet and J. P. Mathieu. Translated by A. Simievic. Pp. xiv+571. (Gordon and Breach: New York, London and Paris, 1976.) £26.

PROFESSOR Mathieu is well known in France as an author of textbooks on the vibrational spectra of molecules and crystals. This book has evolved from one published in 1945. It is a translation of the original French edition of 1970; unfortunately, this is not stated anywhere in the book.

There are ten chapters on theory. They deal with the symmetry and internal structure of crystals, crystal dynamics, the symmetry of vibrations, and the classical and quantum theories of optical phenomena. The last chapter describes applications of the theory to infrared and Raman crystal spectra. There are seven appendices (on group theory and on X-ray and neutron diffraction), and a bibliography giving 185 references. The objective was "to give a systematic survey of the methods used to count the principal vibrations

of crystals, to determine their symmetry, to investigate their interactions with electromagnetic radiation and to establish the selection rules to which they are submitted".

The book has been written in a clear and helpful style, and will be useful to physicists and chemists concerned with the vibrations of crystals. Unfortunately, the translation is not always good—words such as "inequally", and phrases such as "integer multiple" and "allows to reduce their number" are to be found throughout; "et" occurs in the references instead of "and". An old value is used for the velocity of light, and SI units are not always used. There is a reference to Kitaigorodskii's 1961 book rather than to his *Molecular Crystals and Molecules*, published in 1973. There is no discussion of non-linear optical properties such as stimulated Raman scattering and the hyper-Raman effect.

A. D. Buckingham

A. D. Buckingham is Professor of Chemistry at the University of Cambridge, UK.

Linguistic theory

Integrated Theory of Linguistic Ability. By T. G. Bever, J. J. Katz and D. T. Langendoen. Pp. 432. (Harvester: Hassocks, Sussex, UK; Crowell: New York, 1977.) £14.95.

Is linguistics an empirical science like psychology or a theoretical science like logic? Is it, indeed, a science at all? One is bound to wonder about the status of a discipline that has as many schools and schisms as a political movement.

The great revolutionary figure is, of course, Noam Chomsky, the genius of transformational grammar. In 1965, he proposed a grammar, the so-called "standard theory", which formally specifies two different levels of syntactic structure. The surface structure of a sentence segments it into such constituents as noun phrases and verb phrases; its deep structure involves the same sorts of constituents but arranges them in a way that unequivocally identifies the subject and object of the sentence and other such grammatical relations; deep structure is mapped onto surface structure by transformational rules.

Chomsky's syntactic arguments for this grammar were compelling: most of the trouble has arisen over meaning, and the past decade has seen a continuing 'revolution within the revolution'. The standard theory took the deep structure of a sentence as a blueprint for its meaning, and the surface structure of the sentence as a blueprint for its phonological interpretation. But a group of radical linguists has argued that the theory is riddled with internal contradictions: grammar should derive the surface structure of a sentence not from some syntactic intermediary such as deep structure but directly from its meaning.

An alternative and 'revisionary' group, led by Chomsky himself, has progressively developed first the "extended standard theory", which allows both deep and surface structure to contribute to meaning, and then the "revised extended standard theory", which derives meaning solely from surface structure. There are still other alternatives, not to mention the numerous groups of linguists working outside the framework of transformational grammar.

The editors of this book—for it is a book of readings rather than the integrated text that its title page might suggest—are members of the 'revolutionary old guard' who wish to defend the standard theory, which they con-

sider to have been abandoned prematurely. To this end they have pulled together fourteen papers, most of which are by the editors and their collaborators, and most of which have appeared in print before.

The gist of their argument is that many of the phenomena that have seemed to motivate counter-revolutionary developments, in fact, defy linguistic explanation. Rather they are to be explained on the basis of the psychology of speech perception or pragmatic conventions governing conversation. The argument is remarkably persuasive, but its effect on the status of linguistics

is more questionable. Where many theories compete, it is natural to attempt to confront them with a wider set of empirical phenomena. By deliberately diminishing the set of relevant phenomena, the authors might seem to be moving linguistics towards the threshold of the comfortably insulated world of parlour politics.

P. N. Johnson-Laird

P. N. Johnson-Laird is Reader in Experimental Psychology at the University of Sussex, UK.

3-D imaging techniques

Three Dimensional Imaging Techniques. By T. Okoshi. Pp. 403. (Academic: New York and London, 1976.) \$15.00; £10.65.

INVENTORS have been fascinated by the problem of binocular or three dimensional (3-D) imaging for many years; G. della Porta (1540–1615) is reported to have drawn stereo pairs, but Wheatstone was probably the first to make a stereoscope. Since Wheatstone's time, many instruments and systems for producing 3-D images have been invented, several of them described in this book, but it must be admitted that none has yet proved to be the solution to become popular and make its backers multimillionaires.

In this book, there are chapters on vision (a brief treatment stressing depth perception), lens-sheet 3-D pictures (that is, pictures seen through lenticular screens, as in picture postcards and, about 25 years ago, in advertisements on the London underground), projection displays (the various devices for cine projection of 3-D pictures) and, of course, holography. Then there is a chapter on the information content of the different forms of 3-D imagery, and finally a chapter for unclassifiable systems; some of these are connected with computer-generated images and others, such as Gabor's cine projection screen in the form of a gigantic volume hologram, are unlikely to be realised in the foreseeable future. Notable omissions are the cine techniques popular in the early 1950s in which stereo pairs were projected on a single screen either in different colours, to be viewed through appropriately coloured spectacles, or in orthogonal polarisations, to be viewed through polarising spec-

tacles; there is also no mention of the Land Vectograph, a polarisation system used for producing prints or transparencies to be viewed through polarisers.

This book is at its best in the explanations of the technical details of the systems, and this is as it should be since the subject really depends on inventive developments. It is less impressive on the physical principles; for example, in the chapter on information a table gives the bandwidths required to transmit 3-D television by different methods, and figures of order 10^{12} Hz are given for wide-view holography; however, there are no comments on the prospects for achieving such a bandwidth and there is no indication of how the holographic image might be reconstructed. Much of the discussion in the chapter on information is aimed at television transmission but since this is probably many years ahead it is unlikely that the chapter will be very useful. Thus, the book is really an inventor's compendium or review on the subject and it is very good of its kind. Some of the practical details about lasers and holography are out-of-date, but this is because the book was originally published in 1972 (in Japanese). The present translation is very competently done by the author.

One may ask after reading Okoshi whether there will ever be a really good system for showing 3-D images? Perhaps not, although it is risky to prophesy; however, there is another method not mentioned by Okoshi, but known to and practised by the ancient Greeks, which gives quite good results—sculpture. Perhaps it will find a place among the Alternative Technologies.

W. T. Welford

W. T. Welford is Professor of Physics working in the Optics Section of the Blackett Laboratory, Imperial College, University of London, UK.

Hydrogen bond

The Hydrogen Bond: Recent Developments in Theory and Experiments. Vol. 1: Theory. Pp. viii+1-390. Vol. 2: Structure and Spectroscopy. Pp. viii+391-888. Vol. 3: Dynamics, Thermodynamics and Special Systems. Pp. viii+889-1,549. Edited by P. Schuster, G. Zundel, C. Sandorfy. (North Holland: Amsterdam, New York and Oxford, 1976.) Dfl. 450; \$173.75.

It has been a privilege and pleasure to review this treatise. The hydrogen bond is ubiquitous, and the growth in its studies phenomenal. When I recall my student days at Leicester, where Louis Hunter and his group made major contributions using classical methods to the study of the hydrogen bond—and at that time it was thought that this type of interaction occurred only with fluorine, oxygen, and nitrogen—we can realise the enormous strides which have been made in the experimental and theoretical approaches to this phenomenon. Matrix isolation techniques, neutron scattering, magnetic resonance spectroscopies, to name just a few, have added enormous depth and breadth to the subject.

We cannot readily avoid coming across hydrogen bonds in our work; whether we invoke them in proton abstraction mechanisms, or demonstrate them in structural studies. Only very recently it helped to rationalise an apparent anomaly we had observed: a precursor postulated in a room temperature reaction required, after isolation as a crystalline solid, an increase of 100 °C in temperature to give the same product. A crystal structure determination provided the answer (Cameron *et al.*, *Z. Naturforsch.*, **31b**, 1421, 1976): it showed the presence of a 12-membered ring hydrogen-bonded dimer, with some of the shortest recorded O-H . . . N, and N-H . . . S bonds.

These three volumes (detailed in the title) increase progressively in length and cover most aspects of the subject. Deliberately excluded are the mainly biological investigations, and also largely those devoted to the excited state and relaxation kinetics.

I personally found the studies of hydrogen-bonded systems by X-ray and neutron diffraction studies particularly fascinating. The two methods are critically compared, neutron scattering giving the longer X-H bond lengths. This technique also reveals that most hydrogen bonds are not strictly linear, and that in bifurcated hydrogen bonds,

the bifurcation is usually uneven.

The topology of the hydrated proton $H^+(H_2O)_n$ ($n=1, 2, 3, 4, 5$, and 6) is discussed. In most cases, at least two different structures could be considered for a given value of n .

Examples of symmetric $H_5O_2^+$ ions (for example, yttrium hydrogen oxalate trihydrate) and asymmetric $H_3O_2^+$ ions (for example, picrylsulphonic acid tetrahydrate) have been observed by diffraction methods. Similar studies by spectroscopic techniques show the important advances made in this field, and suggest that the symmetric diaquahydrogen ion $(H_2O.H.OH_2)^+$ is rather more prevalent than the asymmetric monoquaoxonium ion $(H_3O^+.OH_2)$.

Major advances in hydrogen-bonded systems have been made using nuclear magnetic resonance spectroscopy and the use of this technique is beautifully demonstrated for the liquid and the solid state.

Perhaps the last two chapters of this treatise, devoted to liquid water and ice respectively, demonstrate most vividly the diversity and complexity to which hydrogen bonding can give rise.

Although the distinguished contributors number almost forty and come from different nationalities, these volumes are written in excellent English, and overlap between chapters is

minimal. The editors must be congratulated. Most chapters cover the literature up to the period 1973-74, some with appendices and notes added in proof up to 1975, a very creditable achievement in an edited treatise. The volumes are beautifully produced and printing errors are scarce. It is a pity that blurring of pp 1,337-1,352, at least in my copy, slightly mars the overall impression. All volumes contain a subject index (covering all three). Volume 3 has also an author index.

Experimentalists (like myself) however, may well find volume 1 heavy going. It is a pity that individual volumes do not seem to be available.

I have so far only considered the quality of this treatise. Alas, we must also pay attention to its cost. A price of more than £100 will deter individual buyers and many libraries in this country. A crying shame as these volumes with their wide, almost universal, appeal ought to be on all library shelves.

I was instructed and stimulated by reading these volumes; I am saddened by the thought, that not enough scientists may be able to share this experience.

Robert A. Shaw

Robert A. Shaw is Professor of Chemistry at Birkbeck College, University of London, UK.

Immunological recipes

Techniques in Clinical Immunology. Edited by R. A. Thompson. Pp. 241. (Blackwell Scientific: Oxford, 1977.) Paperback £6.25.

BLACKWELL Scientific Publications have over the years accumulated a long list of 'titles' in immunology. The standard they and their authors have maintained is generally high. The books range from accounts of the proceedings of specialist conferences to the practical handbook under consideration here. This latter has eleven chapters on techniques commonly used in clinical immunology. It is parochial in that the kind of immunology under consideration is that practised in British hospitals and research institutes—it makes little or no attempt to be international.

Each chapter is written by a person who is involved on a day to day basis with the methods described. Every chapter starts with a short theoretical introduction to the topic before launching onto the collection of recipes which forms the bulk of the text. I am stuck, without doing the cooking myself, in trying to decide whether the

recipes work. They look alright.

The emphasis is toward the classical formulations of immunology rather than the new cell-mediated brand. There is, for example, no chapter on skin-testing. Little is said throughout the book of the indications for any particular test and only rarely about interpretation of results. Perhaps the most thoughtful chapter is that by Irene Batty on quality control. Few of the previous chapters on such disparate matters as the quantification of immune complexes, agglutination of cells or neutrophil leukocyte function tests (an intriguing choice this for an immunology text), give an indication of the way of handling the information gained. Dr Batty lays out in a clear way the basic necessity of quality control charts and describes the area of activity for which standardisation procedures are possible. Relatively few of the other chapters fall into this category.

It is a useful book carefully compiled which is too expensive for a paperback that might sell well.

A. J. S. Davies

A. J. S. Davies is Professor of Immunobiology in the University of London, working at the Chester Beatty Research Institute, London, UK.

Climatic reconstruction

Tree Rings and Climate. By H. C. Fritts. Pp. xii+567. (Academic: London and New York, 1977.) £16; \$35.

THIS is the first book to deal comprehensively with the relationships between tree-rings and climate, and their use to reconstruct past climates. By far the greatest volume of research in this field has been carried out in the United States and the majority stems from the Laboratory of Tree-Ring Research in Tucson, Arizona. Although tree-ring research has been carried out in the arid south-western United States and in Europe for over 50 years, it has been the development of a rigorous statistical approach, and the use of the newer multivariate techniques by Fritts and his colleagues at Tucson, that has transformed tree-ring studies from a dating technique to a climatic reconstruction science of world-wide application.

This book is thorough in its approach and assumes little previous knowledge. In particular, the author reviews the biology of tree growth from the molecular level through cellular to the whole tree and presents this account in a clear manner uncluttered with jargon. Some may feel that this aspect has been overplayed, as nearly 200 pages of the book are devoted to aspects of tree biology. Many scientists approaching dendroclimatology do so, however, from a non-biological background and would find the clear accounts in these early chapters most helpful. Following this biological introduction, the climate-growth relationships are examined and a series of models are proposed to explain a variety of observed relationships. There follows a rather brief account of the mechanics of tree-ring dating from sample collection, preparation and measurement to tests of reliability and the statistics used to describe tree-ring series. Included in this section is a mention of the techniques of time-series analysis that have been applied to tree-ring series.

The following chapters, which contain the real meat of the book, deal with the calibration of ring-width with climate and the concept of the response function. In this area, where the mathematical manipulations are difficult, Fritts succeeds in introducing each new concept and provides plenty of examples to show its application. In particular, he justifies and explains the use of eigenvectors of climatic variables in the multiple regression with ring-widths. He works through a number of examples and offers some

biological interpretations. This technique, which circumvents the problems caused by relationships between the variables, has so far been little used by other workers.

Although the response function of a single tree-ring series can be found and attempts made to interpret it in terms of growth models, it is seldom of any use for the reconstruction of past climate as the factors affecting growth are too complex. A factor such as high temperature may be found beneficial at some times of the year, and detrimental at others. Using several study sites, Fritts shows how multivariate techniques often allow valid reconstructions to be made.

The final chapters concentrate on examples of the more recent multivariate approaches—such as, reconstructions of lake levels, river flow, sea temperature, and even fish catches,

which are controlled by sea temperature. The last chapter gives in some detail the recent attempts by Fritts and his colleagues at pressure reconstructions using large numbers of tree-ring stations in the United States. This chapter also looks in detail at the various techniques of verification used to test the validity of the pressure reconstructions.

The book is well produced and clearly printed, and is remarkably free from minor errors. It should be of interest to all climatologists, and to a wide range of biologists, and its readable style compensates for its considerable length and detail. The explanations of multivariate techniques may well be of value to workers in entirely different fields.

Jon R. Pilcher

Jon R. Pilcher is Lecturer in Palaeoecology at Queen's University, Belfast, UK.

Chemical history

Chemists by Profession: The Origins of the Royal Institute of Chemistry. By Colin A. Russell with Noel G. Coley and Gerrylynn K. Roberts. Pp. x+342, 28 plates. (Open University Press, in association with The Royal Institute of Chemistry, 1977.) £9.50.

THE social history of science may seem a vague or obscure enterprise; but the attempt to discover what it felt like to be a chemist or physicist in the past cannot but be interesting, and is valuable because it casts light on that great majority of scientists who do not have a process, a genus or an equation named after them. This history of the Royal Institute of Chemistry, a body which is this year celebrating its centenary, is more than a benign tribute; it is a critical history, with particular emphasis on the gradual emergence of chemistry as a profession as well as a discipline. It is especially strong on the earliest years of the Institute (which did not become Royal until 1944), and indeed on the years before the Institute was founded—we do not get to the birth of the Institute until nearly half way through the book. This emphasis is completely justified by the authors, because unless one had understood what the position of chemists was before 1877 one would not understand the Institute and its problems, many of which have continued well beyond 1877.

The authors trace chemistry back not only to alchemists but also to assayers and pharmacists; and the tension between academics, chiefly preoccupied with the increase of knowledge but also anxious to promote careers for their graduates, and the

practical men, or practising chemists, has remained ever since. At the British Association, Section B devoted to chemistry dates back to 1835; while in 1841 both the Chemical Society—the first in the world, but many years after the Geological and Astronomical Societies—and the Pharmaceutical Society were founded. The Chemical Society was a learned society, run by academics; but with the rise of chemical industry, the invasion by science of industries like brewing, and the passing of laws against pollution, the industrial chemist and the consultant analyst appeared upon the scene in greater numbers, and demanded professional regulation.

On the one hand, there was pressure (especially from the academics) for high standards; and on the other, pressure to include and register all those working in the field of chemistry, many of whom could not pass examinations of honours degree standard. In the event, it was only in the last third of its century that the Institute took these wider responsibilities as its most pressing concern; in the earlier years its professional functions were narrower than they are now—when it has also merged with the learned society from which a hundred years ago it separated. This history does not answer all the questions that one might want to know; it is generous to previous historians, and also to participants in the history, and does not dilate overmuch upon money, patronage or feuds; but it provides a splendid account of its subject, which will interest not only historians but also scientists.

David Knight

David Knight is Senior Lecturer in History of Science at the University of Durham. He has recently published The Nature of Science (Deutsch, 1977).

obituary

A. J. Haagen-Smit

THE FIELD of air pollution lost one of its most vocal and colourful workers when Professor A. J. Haagen-Smit died on 17 March 1977 of cancer in Pasadena, California.

The objective facts are that Arie Jan Haagen-Smit was born in 1900 in Utrecht, Holland, and obtained his B.A., M.A., and Ph.D. from the University of that city, obtaining the last degree in 1928. After obtaining his doctorate, he was successively head assistant in organic chemistry and lecturer until 1936, when he went to the U.S. as a lecturer in biological chemistry at Harvard, spending the 1936-37 academic year there. In 1937 he joined the faculty at the California Institute of Technology as an associate professor, as a part of a conversion of that institution from a local trade school to its present level of excellence, begun under the late Dr Robert Millikan. Haagen-Smit retired at CalTech in 1971 as Professor of Biochemistry. He also served as executive officer of the department of biochemistry and director of the excellent plant environment laboratory there.

His early research interests were in natural products, particularly essential oils, although he made major contributions to the chemistry of plant alkaloids, plant hormones, and the chemistry of microorganisms. Towards the end of World War II, the Los Angeles area began to experience an increased incidence of haze, accompanied by eye irritation and damage to plants. In the late 1940s this had become a sufficiently frequent occurrence to generate public pressure for its abatement, and it was promptly termed "smog" by some supposed analogy to the more venerable phenomenon then characteristic of London. A sizeable effort was made, derived from this analogy, to control emissions of sulphur dioxide in the area. If anything, the situation got worse.

Concerning the events that followed, Haagen-Smit himself subsequently told several stories. I am personally inclined to credit the one he told me when I first met him, in the mid-1950s. Remember that he was particularly concerned with essential oils, and therefore had a very highly trained nose. He said that the current explanation (that it was all a matter of sulphur emissions) did not fit with what he

smelled on a smoggy day, which was much more reminiscent of oxygenated organic compounds. One day he was leafing through some back copies of *Chemical Abstracts*, and chanced upon a report of a Swiss patent from, if memory serves me correctly, the late 1930s. This patent claimed a process for producing mixed oxygenated compounds from hydrocarbons by photolysis in the presence of nitrogen dioxide. He immediately set up a benchtop experiment with some nitrogen dioxide and a bit of 3-methylheptane, and exposed it to a conveniently available ultraviolet light. After a time, he sniffed the resulting brew, and found that the odour closely resembled that of the outdoors air on the same smoggy day. I remember chuckling with him over the question of whether the holder of the Swiss patent should sue the City of Los Angeles for infringement.

Given these facts, it was obvious to Haagen-Smit that the source of Los Angeles pollution was primarily the automobile and secondarily the petroleum refineries that are interspersed throughout the city. (In fact, I have heard it theorised that the initial wartime problem stemmed from the injudicious selection of a site for a plant to manufacture butadiene, a key ingredient in synthetic rubber.) Needless to say, Haagen-Smit was violently attacked. He had shown that ozone was one of the products of the photochemical reaction. Some of the local industries heavily sponsored a local eccentric who purported to have data showing that the ozone was all of natural origin. Industry also funded local research institutions in the construction of rather elaborate laboratory facilities specifically for the purpose of disproving his theory. An elaborate superstructure, the Air Pollution Foundation, was set up to administer these early contracts. Techniques and instruments were devised or adapted for the measurement of a number of the key ingredients in the Los Angeles atmosphere, and these were produced commercially by local scientific instrument makers, particularly by the Beckman Instrument Company. It is probably no exaggeration to say that modern atmospheric chemistry was born from the researches of Haagen-Smit and of those hired by the affected industries to refute him. While there were a few details needing correction, the sole result of the studies was to

support Haagen-Smit's original theory.

Once the issue was settled by the acquisition of further knowledge, Haagen-Smit received numerous appointments, honours, and awards. He served for a time as chairman of the California Air Resources Board and of the U.S. President's Task Force on Air Pollution, as well as serving as a member of numerous other committees. He worked briefly as a consultant for Southern California Edison, and had a signal role in the development of the technique of reducing nitrogen oxide emissions from power plants by two-stage combustion. He was founding editor of the *International Journal of Air Pollution*, but found the work uncongenial and passed the job on to me at the end of the first year. Nevertheless, he served on the Editorial Advisory Board until last year, through two metamorphoses; the journal is now called *Atmospheric Environment*. Honours included membership in the National Academy of Science and receipt of the Los Angeles County Clean Air Award, the Chambers Award of the Air Pollution Control Association, the Hodgkins Medal of the Smithsonian Institution, the B. Y. Morrison Award of the U.S. Department of Agriculture, the Honor Scroll of the American Institute of Chemists, the Fritzsche Award and the Award for Pollution Control of the American Chemical Society, the Cottrell Award of the Research Corporation of America, the John and Alice Tyler Ecology Award of Pepperdine University, and the National Medal of Science. In his native country he was made Laureate of Labour by the Netherland Chemical Society, and he was made Knight of the Order of Orange Nassau. It is almost unnecessary to add that he belonged to a lengthy list of appropriate professional societies.

However, it is not for his honours that his many colleagues throughout the world will remember. "Haagy." Rather we will remember him for his warm humanity, his unflagging humour and his scientific insight. It would be a signal service to the science historians of the future if someone could take the time and the trouble to begin collecting anecdotes of the man. It is perhaps illustrative of his essential humility that I have found it necessary to consult a half dozen biographical sources to compile the above list of

honours; he rated them sufficiently unimportant that he seems to have given no one source the complete list.

A couple of years ago a joke made the rounds in which God's intent to create heaven and earth was completely thwarted by a demand from the Heavenly Environmental Protection Agency that he first file an environmental impact statement. As I fell asleep the night after learning of Haagy's death, that story suddenly returned to me with the thought, "He's got some help; now Creation can proceed!"

James P. Lodge

Donald Reid

DONALD REID, Professor of Epidemiology at the London School of Hygiene and Tropical Medicine, died suddenly of a heart attack on March 26 at the age of 62. His standing as an epidemiologist had few equals, in Britain or in the world.

He was born in a small Scottish fishing village, the son of a Post Office linesman. The family was poor and survived only through his mother's courage and prudent housekeeping. In later life he still preferred a bus to a taxi, and in research he would think long and hard about efficient study design, and how to salvage something if the primary aim were to be frustrated. If "plan A" failed, he always had "plan B" ready.

After qualifying in medicine he entered RAF Bomber Command in 1939, and there laid the foundations of his own career and of psychiatric epidemiology by analysing the relation between stress and neurotic illness. He showed that breakdown correlated highly with current casualty rates in a particular unit, but not at all with total flying hours. After the war he joined Bradford Hill at the London School of Hygiene and Tropical Medicine, and he succeeded him on his retirement in 1961. In a discipline where data are largely observational and often of poor quality he practised and taught scepticism and meticulous accuracy; but where others discounted the research potential of vital statistics, or surveys using crude clinical examination techniques, he showed that even inferior data can be valuable provided that their errors are recognised and quantified.

Most of his work was in relation to respiratory disease, later extending also to cardiovascular problems. Using national sickness-absence data for postal workers he showed the importance for bronchitis of exposure to air pollution: an excess in absence rates in areas with higher fog frequency was specific for bronchitis and for out-

door workers. By similar methods he identified the tuberculosis hazard for workers in bacteriology laboratories and mortuaries. He was a leading contributor to our recognition of the effects on health of cigarette smoking, demonstrating its interactions with air pollution in the causation of bronchitis, and with other coronary risk factors in the occurrence of heart attacks. He was particularly delighted by his recent election as an honorary fellow of the American College of Cardiology, and at the time of his own death he was working on the predictors of death from coronary heart disease.

His reputation stood as high overseas as at home. His international studies of migrants compared their disease rates with those of their native-born contemporaries in the host country and their siblings at home, thus permitting separation of genetic and environmental influences. He had friends in almost every country, and was much in demand as lecturer, chairman and consultant. Many may have thought that his talks and opinions were given impromptu, but in fact they were always meticulously prepared. Similarly his confident and optimistic manner of belied painful inner self-questioning and nervousness.

His colleagues and students will remember him for his humour (often directed against himself), his warmth and unlimited concern with their well-being, and his complete public and private integrity. He leaves his wife and two daughters; and countless friends in many countries.

Geoffrey Rose

M. S. Vallarta

DR MANUEL SANDOVAL VALLARTA died on April 18 in Mexico at the age of 78 after a long and distinguished career. He was particularly well known for his theoretical work on the geomagnetic effects on cosmic rays.

Together with the late Abbé Lemaitre, Vallarta solved to first order the problem of the cosmic ray intensity distribution in the geomagnetic field. This was done in two stages. First, the "allowed" and "forbidden" directions for cosmic ray particles in the geomagnetic dipole were determined, using the newly devised BUSH differential analyser at MIT, by generalising the earlier treatment of Stormer. Secondly, by an elegant application of Liouville's Theorem, he and Lemaitre showed that for an isotropic cosmic ray flux the intensity at the earth in the allowed direction is the full intensity prevailing outside the geomagnetic field whereas that in the forbidden directions is zero.

This work provided the basis of our understanding of a wide range of

cosmic ray geomagnetic effects and led directly to two particularly important results. First, in predicting an East-West asymmetry in the cosmic ray intensity at low geomagnetic latitudes whose sign depended on whether the primary cosmic rays were positively or negatively charged, it made possible the experimental proof that the primary particles are predominantly of positive charge. Secondly, the calculations of geomagnetic cut-off energies as a function of position in the geomagnetic dipole, which were carried out in great detail by Vallarta and his students, permitted for the first time a determination of the form of the cosmic ray energy spectrum in the geomagnetically sensitive region. Subsequently, the use of Liouville's Theorem, pioneered in this context by Lemaitre and Vallarta, has been extended beyond the field of cosmic rays to the general case of charged particle motion in magnetic fields of all kinds, whether they be laboratory accelerators, plasma containment machines or situations where particles are accelerated or trapped in the naturally occurring magnetic fields of a wide variety of astronomical objects.

During the course of his lifetime Vallarta contributed notably to the prestige and advancement of science and learning generally in Mexico. He occupied a number of important posts in education and the administration of science, both in that country and in the wider international scene. In particular, he was *inter alia* and at various times President of the Mexican National Institute of Scientific Investigation, Member of the National Commission for Nuclear Energy, President of the Latin American Council for Cosmic Ray Studies, Member of the International Commission of Weights and Measures, Sub-secretary for Public Education for Mexico City, President of the Institute for Mexican Cultural Relations in North America and Chairman of the Scientific Council of the International Centre for Theoretical Physics in Trieste. He was the recipient of many academic honours in Mexico, Latin America and elsewhere. These included membership of the Pontifical Academy of Sciences, the Colegio Nacional of Mexico, and the American Academy of Arts and Sciences. In 1952 he was appointed a Knight of the French Legion of Honour.

Manuel Vallarta was outstanding in his generation and for many years he has been a familiar figure to successive generations of cosmic ray researchers. His perceptive and penetrating questions will be missed at future meetings and for all who knew him personally his death represents the loss of a good and kindly friend. He is survived by his wife Maria Luisa.

H. Elliot

announcements

On the Move

Dr J. P. Caen, after a sabbatical year in the department of Pharmacology, University of Cambridge, UK, back to the Research Unit INSERUM 150, Hôpital Lariboisière, 2 rue Ambroise Paré, 75010 Paris, France on 1 July 1977.

Dr N. P. E. Langham, School of Biological Sciences, University Sains Malaysia, Penang, Malaysia, to School of Natural Resources, University of the South Pacific, Laucala Bay, Fiji, on 26 April 1977.

A. Albert, Research Professor in Department of Pharmacological Sciences at State University of New York, Stony Brook, New York 11790, to Emeritus Professor in the Research School of Chemistry, Australian National University, Canberra PO Box 4, ACT 2600, Australia.

Dr S. G. Jennings, formerly in the Department of Physics, Science Laboratories, University of Durham, moved to the Atmospheric Sciences Laboratory, White Sands Missile Range, New Mexico 88001, USA, in November 1976.

Details of changes of department, sabbaticals, where leave will be taken and so on should be sent to On the Move; there is no charge for this service.

Foreign members of the Royal Society elected on 21 April 1977

S. Ebashi, Tokyo University. **I. M. Gelfand**, Moscow University. **E. Hückel**, University of Marburg. **E. Katzir**, Weizmann Institute of Science, Israel.

New Information Services

The Natural Environmental Research Council has set up a Marine Information and Advisory Service (MIAS) which has developed a computerised storage and retrieval system for marine data. For further details contact The Publicity Officer, MIAS, Institute of Oceanographic Sciences, Wormley, Godalming, Surrey, UK.

The Scientific Documentation Centre Ltd has set up weekly Current Awareness Services, handling data on many energy topics. For further information contact Scientific Documentation Centre Ltd, Halbeath House, Dunfermline, Fife, UK.

Person to Person

Wanted, 3-bedroom furnished house or flat for visiting Professor of pathology and wife and 2 teenage children July 1 1977–June 15 1978. Contact G. L. Davis, The Jewish Hospital of St Louis, 216 South Kingshighway Boulevard, St Louis, Missouri 63110 USA.

Exchange 4-bedroom furnished house in Loenen aan de Vecht, 20 min Amsterdam, for 3-4-bedroom house 1 h north or east of New York City 15 September 1977–15 September 1978. Contact G. Mulder, Department of Pharmacology, Free University, Amsterdam, Netherlands.

Marine biologists, aquarists, mariners, naturalists, fishermen. Your observations solicited for scientific work. Author collecting unusual/interesting observations of fresh- and saltwater fish schools, especially observations of spawning. Please give as much detail as possible. Quotations from ships' logs, diaries best. Include location of sighting, date, time of day, kind of fish, behaviour details, observer's name. G. Lorton, Biology Department UVa. Gilmer Hall, Charlottesville, Virginia 22903, USA.

Exchange 4-bedroom detached house in Harpenden, Hertfordshire, 10 min station, 35 min St Pancras, for house in Perth, Western Australia July 1977 to July 1978. Contact G. G. Briggs, Rothamstead Experimental Station, Harpenden, Hertfordshire.

Canadian seeks family accommodation in or near London for one year from August 1977, or exchange house in Montreal. Contact L. Polak, French Department, Birkbeck College, Malet Street, London WC1, or F. McGilly, 4220 West Hill Ave, Montreal 4HB 2S7 PQ Canada.

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

Meetings

13 June–2 July, **Techniques of Developmental Biology**, Rio Piedras, Puerto Rico (G. C. Candelas, Biology Department, University of Puerto Rico, Rio Piedras, Puerto Rico 00931).

20–22 June, **4th International Symposium on Mass Spectrometry in Biochemistry and Medicine**, Riva del Garda, Italy (The Italian Group for Mass Spectrometry in Biochemistry and Medicine, c/o Mario Negri Institute, Via Eritrea, 62-20157 Milan, Italy).

27 June–1 July, **Workshop on Coastal Pollution Control**, Athens, Greece (WHO, Regional Office for Europe, 8 Scherfigsvej, DK-2100 Copenhagen, Denmark).

28 June–1 July, **Working Group on Constraints in Mental Health Services**, Cork, Ireland (WHO, Regional Office for Europe, 8 Scherfigsvej, DK-2100 Copenhagen, Denmark).

29–30 June, **Strategy and Tactics of Control of Migrant Pests**, London (The Royal Society, 6 Carlton House Terrace, London, UK).

30 June, **Laser Processing of Engineering Materials**, Heathrow Airport (C. D. DesForges, Fulmer Research Institute Ltd, Hollybush Hill, Stoke Poges, Slough, Bucks, UK).

30 June–1 July, **The Evolution of Metalloenzymes, Metalloproteins, and Related Materials**, Brighton (N. Birch, Department of Biochemistry, 9 Hyde Terrace, Leeds, UK).

4–5 July, **Conference on Instrumentation for Ground Vibration and Earthquakes**, Keele (The Institution of Civil Engineers, Great George Street, London SW1).

6–7 July, **Profits, Projects and Solar Energy**, London, UK (J. P. Schlesinger, Hyams & Co., 22 South Molton Street, London W1).

7–8 July, **Symposium on Nutritional Aspects of Food and Agricultural Policies in the UK**, Reading (M. R. Turner, Hon. Programmes Secretary, Department of Physiology and Biochemistry, The University, Southampton).

11–14 July, **People and Computers, Computers and People**, Colchester (M. Brady, Department of Computer Science, University of Essex, Wivenhoe Park, Colchester, Essex).

11–15 July, **Conference on Comprehensive Cancer Control**, Copenhagen (WHO, Regional Office for Europe, 8 Scherfigsvej, Copenhagen, Denmark).

11–15 July, **ECM and ECCM for Digital Communications**, Washington, DC (Continuing Engineering Education, The George Washington University, Washington, DC 20052).

11–15 July, **2nd International Conference on The Organometallic and Coordination of Chemistry of Germanium, Tin and Lead**, Nottingham (J. F. Gibson, The Chemical Society, Burlington House, London W1).

12 July, **Symposium on X-ray Diffraction and Spectrometry**, London (The Meeting's Officer, The Institute of Physics, 47 Belgrave Square, London SW1).

12–14 July, **Recognition Marking of Animals in Research**, London (Marking Conference secretary, RSPCA Headquarters, Causeway, Horsham, Sussex).

14–15 July, **Processing, Structure, Properties and Performance of Polymers**, Nottingham (The Meeting's Officer, The Institute of Physics, 47 Belgrave Square, London SW1).

17–22 July, **3rd International Conference on Cyclic Nucleotides**, New Orleans, Louisiana (W. J. George, Tulane University School of Medicine, New Orleans, Louisiana 70112).

18–22 July, **Symposium on Limitations and Potentials of Biological N₂ Fixation in the Tropics**, Brazilia (J. Dobereiner, EMBRAPA, Km 47, Seropedica, 23460, Rio de Janeiro, Brazil).

21–22 July, **Symposium on Plants and the Atmosphere**, Lancaster (Royal Meteorological Society, James Glaisher House, Grenville Place, Bracknell, Berkshire).

23–26 July, **7th International Congress-Conjugation Reactions in Drug Bio-transformation**, Turku, Finland (A. Aitio, Department of Physiology, Kiinamyllynkatu 10, 20520 Turku 52, Finland).

28 July–26 August, **5th International Course on Techniques in Molecular Biology**, Santiago, Chile (J. A. Allende, Faculty of Medicine, University of Chile, Casilla 6671, Santiago 7, Chile).

2–5 August, **Working Group on Evaluation of School Health Programmes**, Bucharest (WHO, Regional Office for Europe, 8 Scherfigsvej, DK-2100 Copenhagen, Denmark).

5–8 September, **2nd International Symposium on Acetylenes, Allenes and Cumulenes**, Nottingham (J. F. Gibson, The Chemical Society, Burlington House, London W1, UK).

5–9 September, **Course in Fluorescent Microscopy**, Oxford (Royal Microscopical Society, 37/38, St Clements, Oxford, UK).

6–8 September, **International Research Symposium on New Processes of Waste Water Treatment and Recovery**, London, UK (The Conference Secretary, Society of Chemical Industry, 14 Belgrave Square, London SW1, UK).

6–10 September, **27th Session of the Regional Committee for Europe**, Munich (WHO, Regional Office for Europe, 8 Scherfigsvej, DK-2100 Copenhagen, Denmark).

13–16 September, **Symposium on Unconventional Photographic Systems**, Oxford (Royal Photographic Society of Great Britain, 14 South Audley Street, London W1, UK).

13–16 September, **4th International Symposium on Nuclear Quadrupole Resonance Spectroscopy**, Osaka, Japan (4th International NQR Symposium, Faculty of Science, Osaka University, Toyonaka 560, Japan).

14–16 September, **3rd National Quantum Electronics Conference**, Southampton (The Institute of Physics, 47 Belgrave Square, London SW1, UK).

16 September, **3rd North West Regional Symposium of the Chemical Society**, Salford (H. Suschitzky, Department of Chemistry and Applied Chemistry, University of Salford, Salford, Lancashire, UK).

18–23 September, **2nd X-ray Powder Diffraction Conference**, Exeter (The Conference Secretary, Phillips Analytical Department, Pye Unicam Ltd, York Street, Cambridge, UK).

19–22 September, **International Conference to Mark the 50th Anniversary of the Discovery of Electron Diffraction**, London, UK (Institute of Physics, 47 Belgrave Square, London SW1, UK).

19–23 September, **2nd International Symposium on the Biological Oxidation of Nitrogen in Organic Molecules**, London, UK (J. W. Garrod, Chelsea College Annexe, 271 King Street, London W6, UK).

19–24 September, **4th Biennial Congress of the International Society for the Study of Behavioural Development**, Pavia, Italy (The Institute of Psychology of the Faculty of Letters and Philosophy of the University, Corso Strada Nuova, 65 27100—Pavia, Italy).

19–24 September, **10th World Energy Conference**, Istanbul (Secretary General of the World Energy Conference, 5 Bury Street, St James's, London SW1, UK).

19–24 September, **8th International Symposium on Earth Tides**, Bonn, FRG (Werke-und Verkehrsamt der Stadt Bonn, Postfach 864, D-5300 Bonn-Bad Godesburg, FRG).

20–21 September, **Population Control by Social Behaviour**, London, UK (Institute of Biology, 41 Queen's Gate, London SW7, UK).

20–22 September, **1977 Autumn Meeting of the Chemical Society**, Aberdeen (The Chemical Society, Burlington House, London W1, UK).

26–28 September, **On-Line Surveillance and Monitoring of Process Plant**, London, UK (Conference Secretariat, 'On-Line Surveillance and Monitoring

of Process Plant', Society of Chemical Industry, 14 Belgrave Square, London SW1, UK).

Walking on two legs

THE regular two-way flow of scientists and technologists that has now been established between the People's Republic of China and the rest of the world has led to some fascinating discoveries about the way in which Chinese research is done and how it is managed. Now the Organisation for Economic Co-operation and Development (OECD) has produced a large-scale document, *Science and Technology in the People's Republic of China*, which attempts to produce an integrated viewpoint on the nature and evolution of China's science and technology system. It should be widely read, particularly by those just about to embark on a visit to China.

OECD's Committee for Scientific and Technological Policy has, of course, been analysing national science policies for many years, generally at the invitation of member countries who have, during the course of the analysis, staged a 'confrontation' with the OECD examiners. In this case, no Chinese were present at the seminar of thirty-odd science-policy experts and sinologists from a dozen countries out of which this report arose. But although it is the work of outside observers and it lacks some detailed information (which probably is all but inaccessible in China itself), the document does most clearly outline the dilemma of organising science and technology in an immense, partly developed nation with major demands both on the urban and rural sector and with a fluctuating but potent ideology in the driving seat.

China seems to live perpetually under the influence of two opposing forces; walking on two legs is how the Chinese describe their attempts to come to terms with these polarities. Elitism and egalitarianism; old and new; 'expertness' and 'redness'; theory and practice; ideology and technology; Mao and non-Mao. And even these poles are very mobile and slippery, as Simon Leys recently demonstrated in the *New York Review of Books* with a mischievous juxtaposition of some of the late Chairman's mutually-contradictory thoughts. Perhaps the fundamental question is whether China is governable at all—if not governed firmly, it is in danger of falling into anarchy and fragmentation. If governed firmly, it is in danger of being strangled by the very

growth of bureaucracy this tends to bring with it', was the way one participant in the seminar put it.

Small wonder then that China's recent scientific and technological past should be marked by grotesque ups and downs. During the Great Leap Forward and the two preceding years (1956–60), university enrolments more than doubled, and the science budget more than quadrupled. But the country wasn't yet equipped to use its graduates and in the next few years enrolments declined by about a third as 'realism' took over and smaller growth was accepted. But then came the next violent change, the Cultural Revolution of 1966. This time universities were all but annihilated for a period of a couple of years as the higher educational system came under attack on all fronts, including its alleged discrimination against workers and peasants. In the recovery period of the past few years students now go through at least two years of manual labour in rural areas before proceeding to higher education.

Science itself was relatively well protected at the beginning of the Cultural Revolution, by the '16-point Directive', which stated 'we must take particular care of scientists . . . who have made great contributions. Efforts should be made to transform slowly their world outlook and their style of work'. This protection did not last, as the pressures for egalitarianism and Chairman Mao's philosophy bit more deeply ('Intellectuals specialising in engineering are better, because they are in touch with reality. Pure scientists are worse, but are still better than those who specialise in the arts. Students of history, philosophy and economics have no concern with studying reality—they are the most ignorant').

The results of these upheavals are now widely known to a growing band of people. And amongst these there has been strong criticism of reduced academic standards, together with muted approval for the science-for-the-people approach. But in the past few years the tide seems again to have been moving slowly the other way, and probably with Mao's death (which came after this seminar had occurred) will move a little quicker. China may start again to walk even more evenly on two legs; this report will provide an excellent guide for the onlookers. □

Persepolis and Miami Beach

Alvin M. Weinberg, of the Institute for Energy Analysis at Oak Ridge, Tennessee, comments on the evils of energy from fossil fuels and nuclear fission.

MIAMI Beach and ancient Persepolis must have as little in common as any two places in the whole world. Yet in the past three months each was the site of a scientific meeting that in an unsuspected way impinged on each other and possibly on our whole future. At Miami Beach 80 climatologists, ecologists, oceanographers, energy soothsayers, and scientific administrators met to discuss carbon dioxide in the atmosphere. At Persepolis, 500 nuclear people met to discuss transfer of nuclear technology. I attended both meetings.

Miami Beach marked the first time that most of the United States workers on the CO₂ problem, plus a sprinkling of European experts, gathered to decide what might be done about the great uncontrolled experiment—the effect of the accumulation of CO₂ in the atmosphere on climate. The atmosphere contains about 700×10^9 tons of carbon as CO₂; its present concentration is 330 parts per million (ppm). The concentration has been increasing at about 1 ppm per year during the 20 years that Professor Keeling of the Scripps Institute of Oceanography has been monitoring it. This increase corresponds to about one-half the total CO₂ thrown into the atmosphere by the burning of fossil fuels.

How much of the increase in CO₂ really comes from burning fossil fuel, how much from clearing of the world's forests? The oceanographers were adamant: there was no room in the oceans to accommodate a contribution from forest clearing that was a significant fraction of the contribution from fossil fuel. The ecologists were less adamant: from what we know about forest cutting, we cannot say whether the biosphere is a net source or a net sink of CO₂. More experiments and observations are needed.

If one assumes the CO₂ increase is caused by the burning of fossil fuel, what is the likely ultimate level of atmospheric CO₂? Since removal of CO₂ to the deep ocean requires 500–1,000 years, the concentration of CO₂ would double in about 300 years, even at the present rate of burning fossil fuel. But if the world's use of fossil energy increases—say sixfold by 2050—then the CO₂ concentration might double in 75 years.

The climatologists, largely basing their conclusions on the Global Circulation Model of Manabe and Wetherald, came close to predicting that a doubling of CO₂ concentration would cause an unprecedented warming of the climate: about 2 °C average, 8–10 °C at the poles. Moreover, the usually invoked stabilisers, especially clouds, did not seem to change these estimates significantly.

What, if anything, can one do about CO₂? Schemes ranging from dumping the CO₂ directly into the deep ocean (a suggestion of C. Marchetti) to planting a trillion trees (F. Dyson) were described. But mostly there was an air of helplessness. If CO₂ is as big a problem as many now suspect, we simply may have to limit our use of coal and other fossil fuels or live with whatever consequences may arise. Prudence dictates that in any case we keep open the world's energy options—solar, fission, fusion, conservation.

Which brings me to Persepolis. The most important paper discussed there was not even on the agenda: it was President Carter's nuclear policy, which was announced on the eve of Persepolis, and which completely dominated the proceedings. How could it be otherwise? Persepolis aimed at facilitating transfer of nuclear technology; President Carter's policy, though domestic, was largely aimed at minimising proliferation and therefore at limiting the

transfer of certain nuclear technologies. No wonder most of Persepolis reacted as though mortally wounded.

Did Persepolis react too strongly? I think it is too early to say. After all, President Carter's proscription of plutonium recycling in light water reactors (LWRs) is simply a continuation of President Ford's policy. It goes beyond the Ford policy in deferring the Liquid Metal Fast Breeder Reactor (LMFBR). Now plutonium recycling in LWRs is only marginally economic in the US; and although it is unclear how the nuclear enterprise will permanently dispose of its wastes unless some reprocessing is allowed, I don't think it was the continued US proscription of plutonium recycling in LWRs that mainly bothered Persepolis.

Nor did President Carter's call for investigation of breeders other than the LMFBR bother me. I have long believed that the entire world locked itself into the LMFBR before it really investigated the alternatives. The real question to my mind is whether the President's policy represents a firm commitment to develop *some* breeder or was only the first step in soft-peddalling all breeder development.

The basic concern at Persepolis was that the new policy may betray an underlying inclination to have done with nuclear energy: let LWRs run their course, and because of the danger of proliferation, do nothing serious about the breeder. And if the breeder is not developed, nuclear energy will wither as our low-cost uranium is used up.

But what then of the necessity of keeping options open, a necessity made urgent at Miami Beach? At Miami Beach the alarm-sayers sense the end of fossil fuels because of CO₂. At Persepolis the alarm-sayers sense the end of nuclear energy, crucified on a cross called proliferation.

I would like to believe that both alarm-sayers are overreacting: that President Carter's policy will really lead to the timely development of several breeders, and that CO₂ somehow isn't the Sword of Damocles pictured at Miami Beach. But these are hopes, not necessary realities.

To weigh proliferation against climatic change is surely beyond human wisdom. Yet there is an asymmetry in these catastrophes, assuming they really exist, that suggests a proper course. The CO₂ catastrophe, if it indeed exists, will occur even if the fossil fuel system works *properly*: it can hardly be avoided short of drastically reducing our use of fossil fuels. Proliferation, by contrast, could be, though not necessarily, a consequence of an *improperly* operating breeder system, that is, one in which technical and institutional barriers to proliferation have failed.

Proliferation stemming from breeders can in principle be forestalled by proper design, both technical and institutional; a CO₂ catastrophe (assuming it exists) hardly can be forestalled except by changing to a non-fossil energy system. It therefore seems clear to me that we turn away from serious development of breeders at great peril. I hope my concerns are without merit, and that the President's policy will lead to greater, not lesser, emphasis on the practical achievement of proliferation-resistant breeder systems. □

Plant a tree and save the world?

An aid to development?

How can science be made to help poor countries?

Alastair Hay looks at part of the UK and Commonwealth effort

TWO international conferences in the past month have tried to resolve the problems involved in dividing the spoils of the world between rich and poor. The first meeting, the Conference on International Economic Cooperation or 'north-south' dialogue in Paris, failed to live up to expectations. The second, the Commonwealth Heads of Government meeting in London last week, had less expected of it. Both have hitherto recognised one way or another a role for science and technology in improving the relationship between rich and poor countries. The difference is that the Commonwealth possesses the means to do something about it.

The final communique from the Paris meeting indicated that the ultimate goal sought by poor countries of a new international economic order was a long way off. No figure was put on a common fund to help stabilise raw material prices, a \$1,000-million aid package fell far below Third World needs, and a general moratorium on Third World debt repayments was refused; on energy the West's goal of discussions between oil producers and consumers was not achieved. But with the countries still talking to each other it was not an unmitigated failure.

Some further progress came from the Commonwealth meeting. And in line with the view that the developed countries will need to provide more aid, the UK Ministry of Overseas Development (ODM) announced a higher contribution to the Commonwealth Fund for Technical Cooperation (CFTC). Through this multilateral development aid fund financed by all Commonwealth governments, the Commonwealth Secretariat supports activities undertaken by such organisations as the Commonwealth Science Council and provides technical assistance in scientific fields to Commonwealth governments. The Commonwealth Science Council (CSC) is the main agency for promoting scientific collaboration between Commonwealth countries, and the increase will have pleased the Commonwealth Secretary General, Shridath Ramphal. In a recent symposium in Brussels on science strategy for Europe he voiced the opinion that "structural change in the world's economic system is the pre-condition of real development". To achieve the new international economic order which the poor countries were seeking, he said, "an important, indeed an essential and integral element,

would be a new, enlightened and dynamic role for science and technology".

The Commonwealth's role in this sphere is not well known, not least because of its minuscule size. The CSC's aim is to increase Commonwealth countries' "national capability to use science and technology for economic and social development", an onerous task for an organisation with a 1976 budget figure of only £100,000 provided by its 26 member countries and £20,000 for project funding by the CFTC. The CSC had its origins in the informal scientific collaboration between Australia, Canada and Britain prior to and during the Second World War. A conference convened by the Royal Society in 1946 placed this collaboration on a more formal basis, and the Council expanded thereafter to incorporate other Commonwealth countries and had several name changes before finally adopting its current title in 1975. By 1972 with the formation of national science research councils in many developing countries most governments were able to define their development problems more specifically, and this helped the CSC to communicate more effectively with them and especially with the research councils.

The Commonwealth Geological Liaison Office, which publishes reports and a news letter containing information on minerals and geology of interest to Commonwealth countries, and the Permanent Commonwealth Collection of Microorganisms, which promotes the expansion of culture collections and their wider use within the Commonwealth, both function under the aegis of the CSC. Further Commonwealth science collaboration is promoted by the Commonwealth Agricultural Bureau and Institutes which disseminate research information in specialised fields of agricultural science. Two more technologically sophisticated science agencies of the Commonwealth are the Commonwealth Advisory Aeronautical Research Council and the Commonwealth Consultative Space Research Committee. And the Commonwealth Foundation exists to provide grants for specialist conferences, study and research visits, bursaries and lectures.

Like all organisations, the CSC has had its difficulties. A Working Group report in 1974 expressed the view that CSC's work should be expanded but with more coherence than was evident

Testing pesticides at the COPR

in the past; in this way it might get across to more scientists in the Commonwealth. Following this gentle upbraiding the CSC streamlined and concentrated its operations. Those of prime concern include standards for engineering and industrial products; industrial research and training; scientific communication and management; mineral exploitation; the technological infrastructure of rural communities; non-conventional energy resources; and preservation and storage of food.

It is a list to daunt many development scientists. The CSC's Executive Secretary since 1972, Gwyn Thomas, who combines his role with that of Scientific Adviser to the Commonwealth Secretary General, agrees that the CSC has a demanding brief, but stresses that its purpose is rather to act as a catalyst than to run specific development projects. The CSC is working towards coverage by organising regional conferences on one or other of these topics, with several interested countries participating. These meetings are held to define common problems and to assist with the formulation of a joint R&D strategy to solve them. It is also encouraging greater sharing between countries of facilities for industrial training. Member countries train technologists in the use of quality standards and there is a move to promote regional harmonisation of standards. As the CSC sees it, quality standards are essential if exports from developing countries are to be sold in highly competitive Western markets.

Crucial concern

The subject of food preservation and storage remains one of crucial concern to the CSC. In view of the Council's limited resources in this field, it is again restricted to exhortation and organisation of meetings. But two UK organisations echo CSC interest in this field and are able to participate actively in development programmes; as a result they provide much relevant

scientific data for food preservation in the developing countries. They are the Centre for Overseas Pest Research (COPR) and the Tropical Products Institute (TPI). Both are scientific units of the UK Ministry of Overseas Development, and as such assist the government of any developing country requesting help. There is a division between their respective roles. The COPR is concerned with pre-harvest food losses, the TPI with the post-harvest period.

The COPR is the newer of these two units. Formed in 1971 by the merger of four ministry units concerned with locust, tropical pesticide and termite research, it started life with its component units having over 60 years' experience in overseas pest control. With this background and the resources available to it—the unit's R&D budget for 1976 was £816,000—the Deputy Director, Tecwyn Jones, found it logical for COPR to "concentrate on pre-harvest loss control and public health fields involving insect vectors".

Jones's experience of pest and insect vector control in the tropics where harvests and health often cannot be guaranteed without pesticide use makes him conscious of the continuing need for chemical control. The objective is to guarantee farmers' crops in the developing world and to protect the health of the workers in the field. However, the COPR is fully conscious of the dangers and shortcomings of persistent insecticides and recognises the urgent need to search for alternative ways of control and use available insecticides more prudently. To this end it is promoting the use of ultra-low volume spraying of pesticides in the tropics. With this technology, sprays effective for the control of tsetse fly can be reduced from 1,000 grams of pesticide per hectare to as low as 6 grams per hectare. The COPR is presently investigating the use of synthetic pyrethroids as alternatives to such chlorinated hydrocarbons as endosulphan, DDT and dieldrin.

Control of insect pests in the future seems in the COPR's view to lie in the use of a combination of insect pheromones—to disrupt mating and reproduction habits—and viruses which are specific to certain pests. Natural parasites and predators may also have a role to play. A COPR programme to test pheromone/virus control has begun and field trials are to be conducted next year in the Mediterranean area, and in East and Central Africa.

On an international scale the COPR collaborates with UN agencies like FAO and WHO. It acts as a reference centre for FAO on locust migratory patterns, and research in the unit on plant resistance to specific insect pests could provide genetic information of

relevance to plant breeders. The unit serves as an international reference centre for WHO for the evaluation of new insecticides for disease vectors such as malaria mosquitoes and tsetse flies, and has an intensive programme to test new molluscicides on the bilharzia parasite.

Broader role

The larger and older of the ODM units is the TPI. With a history going back to 1894 it has amassed considerable expertise in the field of post-harvest processing, preservation, storage and marketing of tropical products. For most of its existence the institute ministered specifically to the needs of the Commonwealth. However, with its incorporation into ODM in 1965, it was able to participate in work directed to the developing world as a whole.

Malcolm Thain is a deputy director of the TPI and is involved in directing the institute's R&D work, which in 1976 had a budget of £1,058,000. He says that the 1975 ODM White Paper 'More help for the poorest' confirmed the TPI in its basic work and that it is generally acknowledged that for Third World crops there is insufficient information on where the losses actually occur in the chain from harvesting to the consumer.

Some of the TPI's research programme is therefore directed towards identifying the weak points in this chain. Inevitably, unfortunate side effects of the green revolution have been identified: varieties of maize especially bred for yield often prove to have poor storage qualities, for example. This has led many Third World farmers to revert to their own lower yielding but better storing varieties. The TPI is thus directing some of their efforts towards the problem of storage of high yield crops, genetic breeding for 'storage properties' as well as yield, and low cost technology for assisting farmers to both dry and store crops. For instance, cassava has a storage life of a few days before

decay sets in. TPI scientists have found that a simple earth clamp, similar to that used for storing potatoes, will preserve the crop for up to 3 months.

Other TPI research efforts are concerned with insect pests, again using pheromones as well as fumigation methods, and quality control trials on those foodstuffs of developing countries which have an export potential. One TPI department of increasing relevance to developing country needs is the Industrial Development Department (IDD) near Culham, responsible for most of the ODM research effort on appropriate technology.

David Adair, the head of IDD, is one of those enthusiasts the field of appropriate technology seems to generate. He laments the fact that there is still insufficient grasp of the essential elegance and simplicity of some of the technologies the TPI is working on. Often because they lack the complicated gadgetry of much of today's sophisticated equipment, the items tend to be regarded with a certain air of condescension. However, Adair is not too concerned. Increasing orders for IDD's products is sufficient confirmation of the need for this technology in the developing world. A few of the unit's developments include a still for bay oil extraction which will run on leaves as fuel, a cashew nut processing plant, sunflower seed, cotton seed and groundnut decorticators, simple milling devices, and maize and coconut shredders. IDD places great emphasis on fuel conservation and devotes much attention to alternative sources of fuel like coconut charcoal and to non-conventional building materials.

Demand problem

Adair's problem—he receives more requests for assistance than he can hope to provide—is common to the TPI as a whole as well as to COPR and CSC. All three concerns publish extensive information about their activities and rely to a considerable extent on publicity to get their message across. But the resources required to meet the needs of the developing world are far greater than those possessed by these three organisations, or indeed by the international organisations or charities.

Development programmes in Third World countries embrace not only science and appropriate technology but sociology, ethology, medicine and economics as well. Integration of these disciplines into aid programmes is now an accepted practice, but personnel and resources are still too limited.

The solution is succinctly put by the Commonwealth Secretary General: "It is not lack of knowledge about what needs to be done, but the will and commitment to do it". □

Corn off the cob

ISRAEL

Exploiting an advantage

Nechemia Meyers learns of the likely prospects for science and technology under Israel's new government

"WE in the Likud realise that resource-poor Israel has a comparative economic advantage in only one sphere—science and technology—and so we will do everything we can to ensure that this advantage is exploited to the fullest possible extent". So says Professor Moshe Arens, the unofficial science spokesman for Israel's new Likud Government.

The Likud's concern with science and technology may stem in part from the fact that it has four men with a technological background in its 45-member Knesset delegation. Apart from Arens they are Professor Joseph Rom of the Haifa Technion's Department of Aeronautical Engineering, Mr Gustav Badian, Secretary-General of the Engineers' Union, and Mr Yitzhak Moday, who has a degree in chemical engineering but specialises in economic subjects.

The Likud does not favour the establishment of a separate Ministry of Science and Technology, however. This, it believes, would be counter-productive. "Instead of pigeonholing these subjects", declares Arens, "we must ensure that every single ministry

is concerned with science and technology, and particularly with exploiting Israel's own technological potential."

In the defence sphere, for example, Arens readily admits that in present circumstances Israel would still be dependent on certain American components, but argues that if there should be an American embargo on the supply of these components, they could be purchased elsewhere or produced at home. He points with pride to the fact that Israel's highly effective missiles, which he helped to develop, have brought in tens of millions of export dollars, and he is certain that many more high-technology civilian products could do the same.

"We are already selling a whole range of sophisticated items ranging from pharmaceuticals and laboratory chemicals to computerised whole body scanners for hospitals and computerised design systems for textiles", he says. "But much remains to be done. Take solar energy, a field in which we have pioneered. Even now Israel uses more solar energy per capita than any other country in the world, and she also sells some solar energy installations overseas. However, if our scientists are given proper encouragement, I'm convinced that they will be able to develop more efficient methods of exploiting solar energy".

According to press reports, Arens

may be put in charge of a ministry or an authority dealing with energy, water, building and other elements of what he calls the country's physical infrastructure. While refusing to comment on these reports, he does stress the Likud's view that the development of Israel's physical infrastructure must be more carefully planned, and its component parts utilised in a more rational manner.

Arens promises that Israel's R&D facilities, whether in agriculture, industry or some other sphere, will get all the support they require both from the Likud government and from private investors, whom the Likud believes it can encourage by creating a better climate for investment. However, the universities, which are almost entirely dependent on public funds, may be in for a tough time—after already suffering a drop of 30% in real income since 1973.

While Arens declines to estimate how much support the universities can expect, he does note that the Likud will have to slash the government budget if it is to reduce inflation (now running at over 40% a year). This means that at least for the next few years "short term targets will have to be given priority over longer-term targets". Being a faculty member himself, Arens doesn't lack sympathy for Israel's institutions of higher learning. But his presentation of the Likud's priorities gives them clear cause for concern. □

BRITAIN

Publish and be dammed

In the continuing debate over Britain's energy policy there is still no shortage of information being published. Chris Sherwell reports

WHILE final preparations were being made for the opening of the Windscale inquiry this week, one of the chief opponents of the controversial project was with impeccable timing publishing a new book seriously questioning Britain's commitment to an electro-nuclear future. It was not the only publication on the energy front, however. The UK Department of Energy (DEN) was busily announcing another set of findings regarding its strategy for developing alternative energy sources, this time for tidal power and particularly the Severn barrage. Four reports were published on this matter alone. The DEN also released a review, prepared at the end of last year, detailing the country's energy policy options.

The inquiry into British Nuclear Fuel Ltd's (BNFL) application to develop land at Windscale for an oxide fuel processing plant was due to open on Tuesday morning in nearby Whitehaven, Cumbria, before Mr Justice Parker, the inspector, and two assessors, Sir Edward Pochin and Professor Sir Frederick Warner. BNFL submitted an outline planning application to the local authorities in February. In accordance with his announcement last December, Mr Peter Shore, Secretary of State for the Environment, ordered the public inquiry to allow examination of health, safety, environmental and planning aspects.

The inquiry, which is expected to last some three months, is widely regarded as a critical test for the future of nuclear power in Britain. On it also hangs the fate of deals worth hundreds if not thousands of millions of pounds for reprocessing other countries' ir-

radiated oxide fuel. BNFL's statement of case, circulated in May, emphasises the conservation and waste control benefits of reprocessing and the economic advantages of taking on overseas business. Opponents, who include Friends of the Earth, the Conservation Society and others, have retained expensive legal counsel and sought to raise funds publicly.

The inquiry was expected to begin with brief opening statements on behalf of BNFL and the various opponents before proceeding later in the week to BNFL's detailed presentation. The basis for the sort of arguments the corporation will then face is contained in *The Fissile Society* by the FOE's energy specialist, Walt Patterson, and published last week*. With the inquiry almost certain to spill beyond the immediate issue of the reprocessing plant itself, the book is a useful articulate distillation of the case against a nuclear future that neatly ties together a historical perspective and the prevailing sense of urgency.

No such urgency is apparent in

connection with the long-standing and increasingly widely supported idea of a barrage across the Severn Estuary in the west country that would harness the energy from the tides. At a press conference to announce publication of results of three special studies relating to the barrage† and another more general report from the DEN§, Dr Walter Marshall, the department's chief scientist, could offer no date for a decision from the DEN's Advisory Council on Research and Development (ACORD) on the next step, a large-scale £1–2-million feasibility study.

This will not have encouraged people like Patterson, who argued strongly last week for a redistribution of Britain's energy R&D effort, and Arthur Palmer, the chairman of the House of Commons Select Committee on Science and Technology, from which a report on the barrage is due out in the coming months along with a separate report on other alternative energy sources. According to a spokesman for NEDECO, the Dutch engineering group which conducted one of the studies, the earliest that work could begin with a decision now is 1982, to allow for four years of preliminary study. Sixteen years later the project could be complete, at a cost variously estimated (depending on whether it is a 'single basin' or 'double basin' scheme) between £2,400 and £3,100 million at today's prices—excluding the turbines.

ACORD is now considering all the reports, which come 12 days after a one-day symposium on the subject in London. None of them examines the environmental effects of a barrage; that, says Marshall, would have proved both difficult and expensive. They were designed to consider, first, the influence of various barrage schemes on tidal levels and currents, and secondly, the technical feasibility of a barrage. The Hydraulics Research Station (HRS) study speaks cautiously of an increase in spring tidal ranges seaward of the barrages of about 1.4 m, but NEDECO speaks of a decrease of similar order. General changes in currents, however, would be small, but navigation, flooding and drainage would all be affected. On the positive side the Institute of Geological Sciences report finds the seabed at the barrage area uncovered by drift and with bedrock exposed. NEDECO's finding is the most positive: the complex project is technically feasible. The problems, therefore, are now economic and political. □

SWEDEN

A developing nuclear policy?

Wendy Barnaby reports from Stockholm on recent developments concerning Sweden's nuclear programme

THE Swedish government is to give credit guarantees for the continued building of the Forsmark 3 nuclear reactor but not for Oskarshamn 3. In a classic case of a 'no-decision decision'—now the norm for the government's handling of the nuclear energy issue—the energy minister, Olof Johansson, said recently that about \$30 million would be guaranteed for Forsmark 3 while the reactor's owners agreed on the pace at which building should be continued. In a couple of months, when the negotiations were expected to be finished, the government would reconsider the question of more guarantees. He himself would not comment on the reactor's development, saying that he did not want to pre-empt the owners' negotiations.

The government gave no reason why guarantees to Oskarshamn had been refused, but a spokesman for the company said that there were two probable reasons. One is that, whereas the Forsmark reactors are 75% state-owned, Oskarshamn is a private company. In order to continue building their reactor without state financial guarantees, the management of Oskarshamn will probably have to approach ASEA-Atom—which is 50% state-owned—for help. The state could therefore gain some indirect control over the project.

The other reason is that the State Power Board, the largest owner of Forsmark's reactors, employs 2,000 workers who have been building Forsmark 2 and who would be unemployed if they could not now build Forsmark 3. The Oskarshamn practice, on the other hand, is to contract out its work. The government could therefore have been hoping to avoid visible unemployment.

Unemployment is very much on the minds of the industrial workers dependent on the reactors for their jobs. Six trade unions have sent a joint letter to the energy minister demanding an immediate, clear decision on the short and long term prospects for the construction of reactors. It is highly unlikely that they will get it. All they can hope for is clearer guidance in autumn 1978, when the government plans to present proposals for a new energy policy up to 1990.

The management of Oskarshamn is planning to go ahead with the construction of the third reactor, even

though it will be delayed now by up to two years. They reason that, if they can arrange their own finances, there is no reason why they should not in future be treated differently from Forsmark 3. The owners of each reactor will, under the law stating the conditions on which new reactors may be built, have to present the government with concrete proposals for the 'completely safe' storage of unprocessed fuel or of highly radio-active waste if the spent fuel is to be reprocessed; and reprocessing agreements will also have to be presented.

Although the Centre Party was elected to the government largely on its promises that it would stop nuclear power in Sweden, it has so far shown no particular hurry to do so. And if it is prepared to entertain the possibility of contributing to Forsmark 3, the Oskarshamn management evidently doubts that it will put in jeopardy the \$330 million-worth of orders placed last year with different sections of local industry for the components of Oskarshamn 3.

There is no more certainty about the reprocessing and storage of spent nuclear fuel than there is about the building of the reactors themselves. If the Ringhals 3 reactor produces any spent fuel before the end of 1979, it will be sent to La Hague in France for reprocessing. Otherwise, according to the technical director of the State Power Board, it will have to be stored without reprocessing. This solution may also have to be adopted for the Forsmark 1 reactor, which so far has no reprocessing agreement for the spent fuel it should begin to produce next year. The State Power Board envisages waste being stored in a central depot until 1995, by which time it evidently hopes that other solutions will have become available.

A second round of test drilling, designed to examine the quality of rock near Forsmark, is now being started by the Swedish Geological Survey on behalf of the companies building reactors. Preliminary results from the first tests, near Oskarshamn, were in general good, showing hard rock with low permeability—the sort of rock that would be suitable for storing nuclear waste. According to a spokesman for the nuclear companies, storage of processed, vitrified waste and the direct deposition of encapsulated fuel elements will be considered. The main geological reports are expected to be ready by 1 October this year, but supplementary reports will be issued during 1978. □

IN BRIEF

Orlov appeal

Almost 600 French physicists have signed a declaration in defence of Professor Yurii Orlov, founder of the unofficial Moscow 'Helsinki monitoring group'. This was announced this week at the close of the 'Orlov hearing', a mock trial staged at the Institute of Physics in London on the eve of the Belgrade review of the implementation of the Helsinki agreements.

Orlov was arrested on 10 February and is being held incommunicado in the Lefortovo prison in Moscow. He has not yet been formally charged, but it seems likely that when a charge is made it will be concerned with the activities of the monitoring group under the articles pertaining to anti-Soviet propaganda.

The case for the defence, presented in London by John Macdonald QC, analysed the 19 major documents on Soviet violations of the Helsinki agreements, maintaining that the content of the documents was true, and believed

by the members of the group to be true. "Witnesses for the defence" included the mathematician Leonid Plyushch, Vladimir Bukovskii, and Marina Voikhanskaya, a psychiatrist who refused to cooperate with the Soviet misuse of psychiatry for political ends.

Employment prospects

The total number of scientists and engineers employed by private industry in the United States dropped by 5% in the first half of the 1970s, according to a study released last week by the National Science Foundation. The first major survey of scientific employment since 1970, the study also indicated that there has been a major shift in employment patterns, with manufacturing industry reporting a 13% drop and non-manufacturing industries indicating an 11% increase in the number of scientists and engineers they employed between 1970 and 1975. The figures refer to all scientists and engineers working in private industry.

Those directly employed in research and development departments declined particularly sharply, from 372,000 in 1970, to 329,000 in 1975—a 12% drop. Though the survey covered a period of economic recession, the decline in the number of scientists and engineers employed by private industry was unexpectedly sharp. Recent indicators suggest, however, that the scientific job market may be picking up a little as the economy has improved.

Cost-of-living for NSF

Unmoved by protestations that academic science in the United States has been suffering from financial undernourishment, the House Appropriations Committee recently recommended that the National Science Foundation (NSF) should get no more than a cost-of-living increase for its support of basic research next year. The committee, which is the most powerful of the Congressional panels which handle NSF's budget, recommended that

RECENT reports that the United States is planning to build a radically new type of nuclear weapon, designed to kill people by releasing vast quantities of lethal neutrons while causing relatively little blast damage to buildings, may have been a bit misleading. Though details of the proposed weapons are shrouded in secrecy, a number of independent experts have told *Nature* that they are unlikely to differ significantly from the small tactical nuclear explosive already deployed in large numbers.

Funds to begin building the device, for use as a warhead on the Lance short range missile, are contained in budget proposals for the Energy Research and Development Administration (ERDA) which are now being considered by Congress. The first official public reference to the weapon came last March when General Alfred Starbird, Assistant ERDA Administrator for National Security, told a Congressional committee that it would be designed to "reduce the blast effect and get the kill radius you want through enhanced radiation".

All nuclear explosions give off energy in two forms: a blast and heat wave which causes physical destruction of buildings and other structures, and withering radiation in the form of gamma rays and fast neutrons (so-called prompt radiation) which can pass relatively easily through the atmosphere and penetrate solid material, including people.

In addition, radioactive debris from the explosive and from material sucked into the blast will later be deposited as potentially lethal fallout. It has long been known that the

Blasted heat

BACKGROUND

relative importance of these effects depends on a number of factors, including the size of the explosion, the design of the explosive, and the altitude at which it is detonated.

In general, the smaller the explosion, the greater is the relative output of prompt radiation. Design is particularly important: according to a book written two years ago by Theodore Taylor, a former weapons

designer, two explosives with the same explosive yield but with different designs could differ by at least a factor of 10 in their output of fast neutrons. In particular, thermonuclear fusion reactions, which take place in hydrogen bombs, are particularly efficient producers of fast neutrons.

Until recently, the chief goal of weapons designers was to produce high-yield explosives which would destroy targets through blast and heat. These are usually fission-fusion-fission devices in which a fission bomb is used to trigger a fusion reaction which in turn sets off a fission reaction in a blanket of uranium surrounding the device. More recently, design has shifted more toward so-called 'mini-nukes', weapons with small explosive yields which could be used with very accurate missiles to knock out small targets. Again, heat and blast would constitute the chief destructive force of the weapon.

The proposed new 'enhanced radiation' weapon is believed to be a modified mini-nuke, possibly a small fusion device, triggered by a low-yield fission explosion, without the surrounding blanket of uranium. The important point to note is that although the weapon is designed to give out relatively large amounts of neutrons, the heat and blast effects would still be substantial—according to some experts they would probably still account for the largest fraction of the weapon's energy output.

NSF should receive \$844 million next year. The administration had requested \$885 million. Virtually all the reduction would be taken from NSF's basic research programmes, leaving only enough for a 6.5% increase, about the same as the rate of inflation. The committee specifically stated in its report that it believes academic science has fared relatively well in the federal budget in recent years, and that a major boost in support is therefore unjustified. The Senate Appropriations Committee, which is often more generous towards NSF, has yet to act.

Catch quotas for whales

Last week, a meeting of the International Whaling Commission's (IWC) Scientific Committee was the focus for the latest exchanges in a long standing argument over how whale catch quotas are determined. A statement by the Committee, that no species of whale

is under threat from extinction, was challenged by Dr John Beddington of York University, one of Britain's delegates to the conference.

Dr Beddington claimed that the basis of the IWC's estimates of catch quotas, the 'maximum sustainable yield', is founded on a false premise. It states that a maximum harvest will be achieved if whale populations are reduced to 60% of their original size. Dr Beddington, however, believes that at this level whale populations will become unstable and may die out.

It is expected that protesters against whaling will be out in force during the Commission's main conference which begins on 20 June.

Tenerife allegation

The attempt to identify the victims of the world's greatest aircraft accident at Tenerife in March has involved "a travesty of justice and a major insult

to the field of forensic sciences in the United States", according to Bill Eckert writing in the latest issue of *Forensic Science* published by Elsevier, Sequoia. He lists "classical mistakes" made by the Spanish authorities in the investigation. The bodies were removed from the wreckage without marking their location, and were embalmed and placed in coffins before identification was complete. They were examined by local public health and forensic authorities who had little knowledge of the procedure; no dentists were available. The bodies were also removed to another country and to a strictly military base using exclusively non-civilian experts. When other than the best available forensic experts are used, Eckert concludes, questions of a medicolegal nature may never be ascertained. This could affect "one of the greatest legal cases in the history of transportation accidents".

It has long been a standard agricultural practice to improve the soil by ploughing crop residues under ground. When I worked on a farm in the 1920s, a popular two-year rotation was to sow oats and sweet clover (*Melilotus alba*), cut the oats to leave a high stubble, let the clover grow to about eight inches the next spring, plough it under and plant maize. The benefits of such procedures were rediscovered by the late Mr Jerome Rodale, a New York City electrical contractor who turned to farming. He coined the names 'organic farming' and 'organic food' in 1942, and popularised them extensively thereafter. He said in 1964 that one MD in California "has cured four cancer cases by putting them on a 100% organic diet". Mr Rodale also used a machine called a 'Theramak' for taking electrical treatments to give himself "more electrical energy".

The definition 'organic' in terms of food production was given by Mr Rodale's son in 1972 at hearings before New York State Attorney General Louis Lefkowitz:

Organically-grown food is food grown without pesticides; grown without artificial fertilisers; grown in soil whose humus content is increased by the additions of organic matter; grown in soil whose mineral content is increased by the applications of natural mineral fertilisers; has not been treated with preservatives, hormones, antibiotics, etc.

The uncleanness of 'antibiotics' to the faithful followers of Rodale seems paradoxical in view of the fact that these organic compounds are produced by moulds. The term 'etc' makes the definition quite elastic. In the hearings, a New York State governmental investigator reported

that a man selling organic fish stated, verbally and on a placard, that it was caught in the pollution-free mineral-rich Atlantic Ocean. One trembles to think of the horrors of

What is organic?

THOMAS H. JUKES

inorganic fish, but, in any event, 'organic' food is a term coined by Rodale and maintained by his successors and heirs. Its popularity reflects the age-old struggle between reductionism and vitalism. Indeed, the legitimate scientific definition of 'organic' as referring to carbon compounds dates back to the concept that they are produced only by living organisms. This idea was annihilated in 1828 by Wöhler, who made urea from ammonia and carbon dioxide and announced he had synthesised urea "without a kidney, a bladder, or a dog". But vitalism lingers on in the

health food shops where fertilised eggs are sold at a 40% premium because of the "spark of life" imparted by the attentions of the rooster, and it is codified in Oregon, where the Department of Agriculture has issued standards for organic foods, containing "not more than 10% of the allowable residues of any pesticide or other synthetic or artificial substance as established by the FDA". Apparently small amounts of pesticides, like a touch of pregnancy, are permissible. Vitalism has now entered the pages of *Nature*, where we read (12 May) that 'Muck is magic'.

A taste panel at the University of Florida rated a large majority of 'regular' foods as superior to 'health' foods on the basis of "colour, flavour, texture, odour, and general appearance". However, 'organic' foods easily win the cash register battle for their sellers; they cost about 82% more than 'regular' foods in a USDA survey in 1972. Consumers can presumably take spiritual comfort in paying more for lower quality without the possibility of detecting an actual difference by analysis. However, a local case of Q fever is attributed to 'natural fertiliser' used in producing 'organic food'.

When my parents named me Thomas they had not heard the expression "I'm from Missouri", but I believe that they knew of the gospel according to St John, 20 v 24-25. In any case, a doubter I remain, despite Kenneth Mellanby's delight in seeing a headline "Ideas of organic farming being taken more seriously," and his evangelical call to nonbelievers in organic food to repent.

Biological macromolecules: outmoding the rigid view

from Barry Robson

X-RAY diffraction has been of immeasurable value in the analysis of the three-dimensional structure of biological macromolecules. However, the structures determined by X-ray diffraction of protein crystals in particular are inevitably biased towards a rigid picture because the molecules are 'frozen' by the constraint of crystal packing and periodicity. Crystallographers are therefore often accused of having too rigid a view of the protein as it actually exists in solution, although this is rather unfair since much useful information about flexibility in solution has been inferred indirectly from crystallographic studies. A recent study by McCammon, Gelin and Karplus in this issue of *Nature*, page 585, however, represents the most significant advance to date in quantifying the flexibility of a protein, and their technique can presumably be readily extended to other macromolecules.

In order to understand the possible implications of their work for the re-interpretation of the rigid crystallographic view, it is first useful to consider the theoretical work of investigators such as Cooper (*Proc. natn. Acad. Sci. U.S.A.* **73**, 2740; 1976). It is obvious that the structure in the crystal need not, in principle, be the same as the favoured structure in solution, although the evidence suggests that they are and implies the dominance of the intramolecular forces in the crystal. It is less obvious, if one forgets basic statistical reasoning, that the crystal structure need not be the same as the average structure in solution. Therefore Cooper has emphasised that, in the statistical mechanical distribution of protein conformations, the mode is not necessarily equivalent to the mean. In other words, although the most probable state of the molecule may be the compact globule observed by crystallographers, the properties

measured in solution may reflect the large number of possibilities for different, relatively open structures, each of which has a low probability but which collectively add up to a high probability. Therefore, although it is important to determine the degree of dynamic variability in a macromolecule, it is also important to establish whether or not this dynamic variability can draw the average conformation away from the most probable which is one hopes that observed in the crystal.

In order to resolve these uncertainties, McCammon *et al.* have carried out a computer simulation of the molecular dynamics in which the theoretical equations of motion of all the atoms in the molecule are solved simultaneously over a period of time, the history of the behaviour of the atoms being recorded for analysis. The system used was the small protein pancreatic trypsin inhibitor (PTI), the solvent being neglected except for four water molecules which are strongly bound in the interior. The structure obtained by X-ray crystallography was used as a starting point, and the atomic velocities were increased to yield an average kinetic temperature of 295 K. Analysis of the resulting trajectories revealed "a rich variety of motional phenomena that occur on the atomic level at ordinary temperatures". The internal motion of PTI was seen to be fluid-like and governed by collisions between neighbouring non-bonded atoms, rather than by rotational potentials governed by covalently bonded atoms. The average root mean square (r.m.s.) fluctuation of all atoms was 0.9 Å, although larger displacements of 3 Å or more occurred in some regions on the protein surface.

The value of 0.9 Å relates to the deviation from the average structure obtained by molecular dynamics. When the r.m.s. of all the atoms from the X-ray structure was considered, the deviation rose to 1.7 Å. This qualifies the relation between the dynamic

mean conformation and the statistical mechanical mode observed by X-ray crystallography, although if the answer is quantitatively well defined, it is not conceptually so clear cut. The authors state that the time-averaged structure is "near the X-ray structure but not identical with it".

The results are certainly not bad news for crystallographers: although the shift to the calculated time-averaged structure from the crystal structure might be to some extent an artefact of the models used for interatomic forces and of the neglect of solvent, a more correct treatment could undoubtedly bring about only better agreement. On the other hand, those who favour a flexible picture should also be reasonably happy as the molecule had quite clearly been sampling a series of neighbouring conformations whose average was not identical with the X-ray structure.

Not all of the PTI molecule was shown to be equally flexible. The largest fluctuations, apart from those due to the flexibility of side chains at the protein surface, came from the two ends of the backbone and residues 25-28 which loop out of the molecule. The latter showed particularly interesting behaviour, undergoing changes in shape superimposed on an oscillation with a period of 6 ps. On the other hand, regions of the chain which form into such characteristic local arrangements as α helix and β -pleated sheet have significantly smaller fluctuations than average. However, even these features showed oscillatory behaviour, the β -pleated sheet region participating in a low-frequency 'rippling motion'.

Despite the possible inaccuracy of the potential functions used, the neglect of individual hydrogen atoms, and the neglect of the surrounding solvent, these calculations show fairly clearly that PTI is able to wander through a large number of alternative conformations but is prevented by high energy barriers from wandering too far from the observed X-ray structure. This is

Barry Robson is a lecturer in the Department of Biochemistry in the University of Manchester.

probably fortunate, because the neglect of the solvent is likely to be increasingly dangerous as conformations less and less like the X-ray structure are sampled.

Molecular dynamics and the nucleic acid controversy?

The potential for future application of molecular dynamics and related techniques seems enormous, and is likely to be as important in the field of nucleic acid structure. Of particular interest would be its application to the current heated debate concerning the 'zipper' model for DNA as an alternative to the classical double helix (Rodley *et al. Proc. natn. Acad. Sci. U.S.A.* **73**, 2959; 1976). X-ray diffraction of DNA fibres, as opposed to protein crystals, provides more ambiguous information with which the zipper model also seems to be in good agreement. While the double helix has the advantage of being, in some sense, aesthetically more pleasing, particularly because many other biological macromolecules form helical structures, it has to be remembered that nature does not work under an Arts Council grant. Any DNA structure, however bizarre, is likely to coexist in solution alongside the double helix if accurate energy calculations show it to be of comparable free energy, providing molecular dynamic calculations also show that the alternative structure is kinetically accessible. Although the zipper model appears to contain some bad interatomic clashes, there is a very real possibility that these can

be dynamically relaxed. This could be dynamically feasible; to make it kinetically feasible, the zipper and double helix arrangement would have to be able to coexist in the same strand with easy transitions from one arrangement to the other. While both criteria seem to be satisfied, the transition to a zipper structure can only occur by removal of right-handed twists from the ends of the DNA double helix. Although the current zipper model proposed alternate right and left-handed screw orientations of the chain of five nucleotides apiece, there seems no reason why multiples of five cannot be used, or sections employing different multiples of about five interspersed with classical double helix. Thus there is room for speculation that, while chromosomal DNA may be always double-helical, short sections of DNA in solution may show dynamic fluctuations to regions of zipper form, and greatly modify certain solution properties such as the kinetics of unwinding of short DNA *in vitro* (J. P. Day, personal communication). The important point is that all such conjectures can only be quantitatively justified, in the absence of conclusive experimental data, by theoretical tools related to molecular dynamics. The zipper-double-helix controversy, providing it is not debased by confining it only to the chromosomal DNA *in vivo*, is specifically a problem in molecular dynamics, and the machinery developed by workers like McCammon, Gelin and Karplus is available for resolving it. □

Hepatitis B vaccines

from Arie J. Zuckerman

VIRAL hepatitis has now been identified as a major public health problem occurring endemically in all parts of the world. In recent years, progress in the specific diagnosis of viral hepatitis has proceeded to such an extent that it has revealed a new type of hepatitis which is unrelated to hepatitis A (infectious or epidemic jaundice) or hepatitis B (referred to in the past as serum hepatitis). Precise virological criteria for this new form of hepatitis are not yet available.

The importance of hepatitis B is emphasised by its effects on every field of medical practice, the impact that it has on blood transfusion services and its association with chronic liver disease including cirrhosis and in some regions of the world with primary liver cancer. In addition, infection with hepatitis B virus, particularly in early life, may be

followed by the persistent carrier state. The carrier state may be associated with liver damage, and the world reservoir of carriers at present is estimated to number about 120 million.

Active immunisation against hepatitis B is needed for groups which are at greater risk of acquiring this infection. These groups include individuals requiring repeated transfusions of blood or blood products, prolonged in-patient treatment, patients who require frequent tissue penetration or need repeated access to the circulation, patients with natural or acquired immune deficiency and patients with malignant diseases. Viral hepatitis is an occupational hazard among health care personnel and the staff of institutions for the mentally retarded. High rates of infection with

hepatitis B occur in drug addicts, homosexuals and prostitutes. Persons working in high endemic areas also suffer an increased risk of infection. Women of childbearing age in areas of the world where the carrier state in that group is excessive, are another segment of the population requiring immunisation in view of the increased risk of transmission of the infection to their offspring. Some authors also include military personnel. Consideration will also have to be given to people living in certain tropical and sub-tropical areas in poor socio-economic conditions and where hepatitis B infection is prevalent.

In view of the repeated failure to grow and passage hepatitis B virus (and indeed hepatitis A virus) serially in tissue culture, it has not been possible to develop a conventional vaccine against hepatitis. Attention has therefore been directed towards the use of other preparations for active immunisation. The foundations for such hepatitis B immunogens were laid by the demonstration of the relative efficacy of diluted serum containing hepatitis B virus heated to 98°C for 1 minute in preventing or modifying the infection in susceptible volunteers (Krugman *et al. J. Amer. med. Ass.* **217**, 41; 1971). However, the use of heated whole serum or plasma is unlikely to be licensed for general use.

Hepatitis B small particle vaccines

Since hepatitis B surface antigen, the essentially protein coat of the virus, leads to the production of protective surface antibody as shown in experimental studies and serological surveys, the possibility of using purified 22-nm spherical surface antigen particles is attractive. Such experimental vaccines have been prepared from the plasma of apparently healthy carriers of this antigen. Human hepatitis B infection has been transmitted successfully to chimpanzees, and although the infection is mild, the biochemical, histological and serological responses in the chimpanzees are very similar to those in man. Sensitive laboratory tests are now available for the several markers of hepatitis B infection and these provide the means of monitoring vaccines. Limited numbers of susceptible chimpanzees have been shown to be protected by 22-nm particle vaccines that had been treated by heat or with formalin. Preliminary small-scale safety tests of such experimental subunit particle vaccines in volunteers are now in progress.

Arie J. Zuckerman is Professor and Director of the Department of Medical Microbiology and the WHO Collaborating Centre for Reference and Research on Viral Hepatitis at the London School of Hygiene and Tropical Medicine.

Last year, an experimental, partially purified subunit hepatitis B particle vaccine was administered to patients and staff of a haemodialysis unit. The study did not include a control group, but a marked difference in the incidence of hepatitis B infection was observed subsequently between the immunised group and a group of patients and staff who had not received the vaccine (Maupas *et al.* *Lancet*, i, 1367; 1976).

Although it is generally accepted that the viral subunit preparations when pure are free of nucleic acid and therefore non-infectious, the fact that the starting material for their preparations is human plasma obtained from persons who are persistent carriers of the surface antigen, which is a marker of hepatitis B virus, means that extreme caution must be exercised to ensure their freedom from all harmful contaminating material (World Health Organisation *Tech. Rep. Ser.*, No. 570; 1975). Some concern has also been expressed over the possible induction of harmful immunological reactions to host components, including pre-existing structures of the liver cells, which may be present in such particulate vaccine preparations (see Zuckerman *Nature* 255, 104; 1975; *Lancet* i, 1396; 1976), but reactions of this type have not been observed with the highly purified experimental vaccines in the small number of chimpanzees and individuals immunised so far. The WHO Expert Committee on Viral Hepatitis has recently proposed certain minimum criteria and guidelines for the preparation of hepatitis B vaccines (World Health Organisation *Tech. Rep. Ser.*, No. 602; 1977).

Hepatitis B polypeptide vaccines

Attempts are also being made to prepare vaccines from the constituent polypeptides of the 22-nm spherical particles of the hepatitis B surface antigen. Vaccines prepared from such polypeptides would have an added margin of safety since they would be even less likely than the 22-nm particle subunit vaccines to contain infectious virus or contaminating host proteins that might lead to untoward autoimmune reactions in some individuals (see *Nature* 246, 445; 1973). The potential use of antigenic polypeptides derived from hepatitis B surface antigen is under investigation in several laboratories. A number of these polypeptides are immunogenic and stimulate antibody formation in experimental animals to the group-specific antigenic determinant (Shih & Gerin *J. Immun.* 115, 634; 1975) and subdeterminants of the surface antigen (Dreesman *et al.* *J. Virol.* 16, 508; 1975; Gold *et al.* *J. Immun.* 117, 1404; 1976). Certain of the separated polypeptides also induced a

cell-mediated immune response in experimental animals. In addition, a low molecular weight polypeptide component elicited a cell-mediated response to normal human serum, suggesting that at least one integral component of the surface antigen may contain or be intimately associated with an antigenic determinant related to a human serum protein (Cabral *et al.* *Infect. Immun.* 12, 564; 1975).

The major problems with polypeptide vaccines at present are difficulties in obtaining sufficient quantities of the peptides in pure form and the relatively poor immunogenicity of the polypeptides when compared with the small particles.

Synthetic hepatitis B vaccines

An extension of the use of polypeptide immunogens is the isolation and structural identification of a small surface antigen peptide. This peptide could conceivably be synthesised, function as a hapten, and, when coupled to a suitable carrier may serve as a vaccine. A step in this direction has now been reported by Peterson and his colleagues (*Proc. natn. Acad. Sci. U.S.A.* 74, 1530; 1977). In order to elucidate the structure of the surface antigen, it is essential, of course, to identify its proteins and other components, and much effort has been devoted to this work in many laboratories. Peterson *et al.* describe the identification of two major bands of polypeptides, with molecular weights of 22,000 and 28,000 respectively, and other bands with molecular weights of 16,000 and 40,000–90,000. The purified bands from the 22,000 and 28,000 molecular weight bands had essentially identical amino acid composition to each other and to the intact surface antigen. The most notable feature was the large amount of proline and half-cystine and a large percentage of hydrophobic residues. The amino-terminal and carboxy-terminal sequences of amino acids in these two major polypeptides, which accounted for 75% of the total protein, showed that hepatitis B surface antigen with determinants *adw* consists of a single major polypeptide chain or two homologous polypeptide chains that differ only in limited areas of their structure. The difference in the molecular weight of these two components is due to the carbohydrate moiety of the glycoprotein of the second band. Injection of the 22,000 molecular weight polypeptide emulsified in Freund's complete adjuvant elicited an antibody response in guinea pigs. Antibodies were produced to the group specific determinant and to one of the major subdeterminants of the surface antigen. The 28,000 molecular weight polypeptide, however, did not induce an antibody response and it is suggested

that the discrepancy in the immunogenicity of the glycosylated peptides reported by Dreesman *et al.* and Shih and Gerin (see above) could have been due to contamination of the two major polypeptides.

The momentum towards the production of unconventional hepatitis B vaccines is being maintained, and it would be imprudent to speculate whether successful cultivation of hepatitis B virus in tissue culture, which will lead to the development of ordinary vaccines, will be achieved before a synthetic vaccine appears on the horizon. □

DNA-protein interactions

from Michael Spencer

TWENTY-FOUR years after the unveiling of the Watson-Crick model for DNA it is still unclear how most of its associated proteins interact specifically with it. There are two basic problems: first, how particular DNA base sequences might be recognised by corresponding protein structures, and second whether the protein backbone could adopt a repeating secondary structure to match that of double-stranded DNA. The second of these questions is the subject of a recent paper by Church, Sussman and Kim (*Proc. natn. Acad. Sci. U.S.A.* 74, 1458; 1977).

Their approach has a lineage going back to 1955, when the group led by Wilkins suggested (on X-ray diffraction evidence) that in nucleoprotamine there is an extended polypeptide chain following the narrow groove of the DNA B structure (*Nature* 175, 834). This model was, however, relevant only to a limited class of nucleoproteins, because it relied for its stability on electrostatic interaction between DNA phosphate groups and oppositely charged arginine side-chains. Church *et al.* are interested in whether in other cases, such as the *lac* repressor-operator complex of *Escherichia coli* and the histone-DNA complex, there might be an alternative stabilising mechanism which would "set the stage for the specific recognition to take place".

The new work follows an earlier proposal by Carter and Kraut (*Proc. natn. Acad. Sci. U.S.A.* 71, 283; 1974) that the interacting protein might adopt not a single-chain structure but a two-stranded β -chain helix. These authors

Michael Spencer is a Research Fellow in the Department of Biophysics at King's College, London.

had been struck by the observation of Chothia (*J. molec. Biol.* **75**, 295; 1973) that β -pleated sheets in proteins often adopt a right-hand twist, because this gives a lower free energy than the planar form. Carter and Kraut discovered that such a twist enabled a β -chain duplex to wind neatly round the outside of a nucleic acid helix. They decided, however, that the model was plausible only for the interaction of proteins with double-stranded RNA (not DNA) in the A form; it was then possible to form hydrogen bonds between the ribose 2'-hydroxyls and the polypeptide carbonyl oxygens.

Carter and Kraut were less concerned with present-day nucleoproteins than with a hypothetical ancestor formed in the prebiotic soup. Church *et al.*, more firmly rooted in modern times after the successes of their group with tRNA structure, persisted in trying to build models that would work for DNA in its biologically relevant B form. In order to match the two-fold symmetry of DNA they restricted themselves to antiparallel pairs of protein chains, but this still left them with two possibilities: the adjacent polynucleotide and polypeptide chains could run either antiparallel (type A) or parallel (type P). Polarities are defined here as running from 5' end to 3' end in a strand of DNA, and from NH₂ terminus to COOH terminus in the protein.

Both models were successfully built, using modern techniques of refinement, to incorporate stabilisation by hydrogen bonds from protein NH groups to the 3'-oxygens of the DNA backbone; this utilised all the free NH groups, half of the total being occupied with holding together the β -chain duplex. To obtain good stereochemistry it was necessary to modify the DNA structure, but in the case of type P the distortions were not serious, the atoms of the sugar-phosphate backbone were moved by no more than about half an Ångström unit. To justify the existence of type A models the authors have to invoke the possible existence of considerably distorted DNA structures, but the only evidence for these comes from some rather controversial work by Bram and Tougaard on fibre diffraction patterns (*Nature new Biol.* **239**, 128; 1972). At least some of the unusual patterns reported are now known to arise only with contaminated DNA (Selsing & Arnott *Nucleic Acids Res.* **3**, 2443; 1976).

Within the β -ribbon alternating side-chains project outwards in the models, so that basic residues could bond to DNA phosphates as in the 1955 proposal. The other alternating sidechains point inwards towards the narrow groove of the DNA, where they could be involved in recognition of the base

sequence. The authors hazard no guesses about how this might be achieved, but they helpfully provide atomic coordinates for aspiring model-builders to try their luck on the problem. Some possible interactions have already been described by Seeman, Rosenberg and Rich (*Proc. natn. Acad. Sci. U.S.A.* **73**, 804; 1976).

The weak feature of all this is, of course, the lack of direct evidence that any such structure exists *in vivo*, or *in vitro* either for that matter. Church *et al.* point out that sequence studies predict β -regions at the DNA-binding end of the *lac* repressor; they also quote evidence supporting the idea that binding occurs in the narrow groove of DNA. What is needed, however, is some crystallographic proof. If current rumours emanating from the eastern counties of England are correct, we may soon have a model of the nucleosome which will shed some light on the matter. A further possibility is that someone will be able to produce fibres of DNA complexed with a pure β -ribbon, rather than with whole proteins containing only limited regions of such a structure. If that happens it will be a cue for old-timers to blow the dust off their fibre-diffraction cameras, and to analyse a new and important structure. □

Sorting out the flu genes

from T. Barrett

THE influenza virus, apart from its importance as a human pathogen, is of great interest to virologists because of some unusual features of its molecular biology. Its surface antigenic determinants—the haemagglutinin and the neuraminidase—are constantly changing, leading to periodic influenza epidemics. When cells are coinfecting with different influenza strains recombinant strains are readily produced. This latter property led to the speculation that its genome was segmented, a fact recently confirmed by several laboratories. The genome consists of eight distinct single-stranded RNA segments (McGeoch *et al. Proc. natn. Acad. Sci. U.S.A.* **73**, 3045; 1976; Pons *Virology* **69**, 789, 1976; Ritchey *et al. J. Virol.* **18**, 738; 1976). The virus is negatively stranded, that is, the virion RNA (vRNA) must first be transcribed into complementary RNA (cRNA) before it can be translated into viral proteins.

It was assumed that each vRNA segment represented a single gene since eight virus-coded proteins could be identified in infected cells. These proteins are the three P proteins, thought to have some function in virus transcription and replication, the surface antigens, haemagglutinin and neuraminidase; the matrix protein associated with the virus coat, the nucleoprotein associated with the RNA and finally a non-structural protein which performs some unknown function in infected cells but which is not found associated with the mature virus particle. Both the P proteins and the nucleoprotein are associated with the vRNA in the mature virus particle and can be isolated as a complex which is active in cRNA transcription (Rochovansky *Virology* **73**, 327, 1976).

Preliminary assignment of the gene-protein product relationship was based on the protein size, and the coding capacity of the vRNA segments (Ingls *et al. Virology* **74**, 489, 1976). However, there is room for considerable error in this approach and recent work has focused on getting more definite evidence for the gene-protein product relationship. Comparison of the electrophoretic mobilities of the vRNA segments and the virus-coded proteins of several influenza strains demonstrated significant strain differences, allowing the parental origin of both the vRNA segments and the virus-coded proteins to be determined in recombinants. Palese and his coworkers (for review see Palese *Cell* **10**, 1; 1977) have used these electrophoretic differences to map the gene functions of each RNA segment for two influenza strains—PR8 and HK. Analysis of recombinants which differ from either one of the parental types in one (or few) RNA segments allows one to deduce the gene product of this segment by assignment of the parental origin of the viral proteins. The results obtained with this technique confirmed that the gene order on polyacrylamide gels does not necessarily allow one to assign the protein coding function in order of size. For example in the two strains used in these studies, the fifth RNA segment (in order of electrophoretic mobility) of HK codes for the neuraminidase while in PR8 this segment codes for the nucleoprotein. In both strains the slowest moving RNA segment codes for the third largest protein. The technique, however, is time consuming in that suitable recombinants are required and to repeat the procedure on other influenza strains would require a great deal of effort. Recently a rather elegant and more rapid method of assigning gene functions to particular RNA segments has been developed by a group at Cambridge. Their approach to the problem exploits both the seg-

T. Barrett is in the Department of Pathology in the University of Cambridge.

mented nature of the genome and its negative strandedness (Inglis, McGeoch & Mahy *Virology* **78**, 522; 1977). Individual mRNA functions can be selectively removed by hybridising total infected cell RNA with isolated individual vRNA segments. The individual vRNA segment will hybridise only with its complementary RNA, which acts as a message for a particular protein, and so make it unavailable for translation in a cell-free protein synthesising system. By analysing the protein products of the cell-free system, the protein for which a particular gene segment codes can be deduced by its reduction or total absence. This novel approach to the problem can be extended to any influenza strain and to other negative strand viruses. Another application which the authors suggest is the identification of gene coding functions of DNA restriction fragments. Since DNA-RNA hybrids are more stable than DNA-DNA hybrids in formamide the technique could be used to fish out mRNAs coded by particular DNA fragments. □

Giant haloes explained

from P. E. Hodgson

A POSSIBLE explanation has recently been proposed for the so-called giant haloes that are sometimes found in mica. The haloes are formed by alpha particles emitted from small inclusions of radioactive minerals inside the mica. These alpha particles ionise most strongly, and therefore cause the most damage, towards the ends of their paths, and so each inclusion is surrounded by a spherical shell of damaged mica, the radius of the shell corresponding approximately to the range of the alpha particles in the mica. In a thin sheet of mica, the region of damage appears as a circle, and the discoloured region of mica is called a pleochroic halo.

Many such haloes have been studied, and most of them have radii that correspond to the energies of the known alpha particles from radioactive minerals. However some haloes were found of much greater radii than these, indicating alpha particles of higher energy than any that are known to be emitted from radioactive minerals. These were called 'giant haloes', and it was conjectured that they might be due to the radioactive decay of superheavy nuclei with nuclear charges much greater than any known nuclei.

P. E. Hodgson is Lecturer in Nuclear Physics in the University of Oxford.

Cumulative alpha and proton ionisation as a function of distance from the centre of the halo. The arrows indicate the critical ionisations corresponding to the inner and outer edges of the halo.

Last year Gentry and colleagues irradiated with 6 MeV protons some inclusions of the mineral monazite that were associated with giant haloes, and found gamma rays were emitted that they associated with superheavy nuclei of charges 116 and 126 (*Phys. Rev. Lett.* **37**, 11; 1976; *Nature* **261**, 627; 1976). Later work, however, showed that these gamma rays can be attributed to the small amounts of cerium often found in this mineral, and extensive studies in many laboratories failed to find any evidence that there was any detectable amount of superheavy nuclei in other specimens of the mineral monazite (*Nature* **265**, 496; 1977).

This work effectively disposed of the claim that superheavy nuclei had been found, but there still remained the puzzle of the origin of the giant haloes. Did these indicate the presence of superheavy nuclei in such small amounts, or with such a short lifetime, that no trace of them remains in the present inclusions, or do they have some other explanation?

An alternative explanation of giant haloes has recently been proposed by Von Wimmersperg and Sellschop of the University of the Witwatersrand in South Africa (*Phys. Rev. Lett.* **38**, 886; 1977). They suggest that the giant haloes are formed when the mica contains some water. The alpha particles emitted from known radioactive minerals then collide with the protons in the water and knock them onwards. Since the rate of ionisation and hence the rate of energy loss is proportional to the square of the charge, protons have a much greater range than alpha particles of the same energy and so the knocked-on protons have on the average a much greater range than the alpha particles, and thus produce

haloes of greater radius.

Such a suggestion can be checked by calculating the radius of a halo that might be expected to be produced by a known radioactive mineral embedded in waterlogged mica. The cross sections for proton-alpha collisions are well known, and so it is quite straightforward to calculate the ionisation, and hence damage to the mica, that can be produced in this way. The calculated curve of ionisation as a function of radial distance from the inclusion is shown in the figure. The outer edge of the halo that would be produced by such a distribution can be estimated from the known threshold ionisation for alpha particles. The inner edge of the halo is determined by a reversal process that sets in above a certain level of ionisation; the mica becomes clear again, probably due to some annealing process. This is necessary for the observation of haloes by the proposed mechanism, since the ionisation goes on increasing towards the centre of the halo.

Assuming that the mass fraction of water in the inclusion is 0.3, Von Wimmersperg and Sellschop calculate that the inner and outer diameters of the haloes produced in this way are about 43 μm and 80 μm , compared with the measured values for giant haloes of 42 μm and 85 μm respectively. These results were obtained from reasonable assumptions relating to the proposed mechanism, without any attempt to adjust them to give an optimum fit. This certainly shows that the proposed mechanism is able to give haloes of approximately the required dimensions, but it still leaves some questions to be answered. It is not mentioned whether there is any evidence for such quantities of water in mica, though of course even if none were found it could always

be maintained that the water had been lost after the giant halo had been produced. It might also be thought that there should be some evidence of the halo produced by the alpha particles themselves, but as shown in the figure this would be removed by the annealing process at high levels of ionisation. $\square$

Muonium hyperfine structure

from Peter Knight

THE muon is a curious particle. It behaves in all respects like a heavy electron, yet there seems to be no explanation of the large ratio of the muon mass to the electron mass. The atom muonium, consisting of a positive muon and an electron, is the simplest system available for precise investigation of the interactions between these so nearly identical particles. Everything we currently know about muonium is completely specified by Quantum Electrodynamics (QED) and the Bethe-Salpeter relativistic two-body equation. Its hyperfine structure is similar to that of hydrogen, but avoids problems of hadron structure so a precision measurement of the muonic hyperfine structure (hfs) checks leptonic QED to high accuracy and could perhaps indicate differences between muons and electrons. V. W. Hughes of Yale University has undertaken a systematic programme of precision experiments on muonium for the past 20 years, and with 11 co-authors has recently reported some greatly improved results on the ground state hfs (Casperson *et al. Phys. Rev. Lett.* **38**, 956; 1977).

Past work on the comparison of experiment with theory for muonium hfs has been limited by uncertainties in fundamental constants such as the fine structure constant α (this was most important), the velocity of light c and the Rydberg constant R_∞ . These constants are now known to higher accuracy. Experimental work was limited by the number of muonium atoms available. The basic principles underlying the latest experiment have remained more or less unchanged from earlier work, and the improvement in accuracy has been made possible by using the higher muon intensity produced by the Los Alamos 'meson factory' LAMPF. Muons are produced by the parity-violating pion decay $\pi^+ \rightarrow \mu^+ + \nu_\mu$ and are spin-polarised with the muon spin direction opposed to the linear momentum. Parity violation not only provides polarised

muons but also provides an elegant monitor of the subsequent evolution of the muon spin. The positive muon decays into a positron and two neutrinos with the positron emitted preferentially along the muon spin direction (and therefore in an opposite direction to the muon momentum). Atomic muonium is formed by charge capture from a krypton gas target at 1.7 and 5.3 atmospheres. The charge capture process does not alter the muonic spin directions so that spin polarised muonium is formed.

In zero magnetic field there are two hyperfine structure levels—a triplet state with total angular momentum $F = 1$ and a singlet state with $F = 0$ separated from the triplet by the hyperfine structure interval $\Delta\nu$, caused by the magnetic interaction between the spin magnetic moments of the electron and the muon. In the strong magnetic field (13.6 kG) used by Caspersen *et al.* the interaction of the magnetic moments with the external field is large compared with $\Delta\nu$. Figure 1 illustrates the magnetic-field dependence and state-labelling of the relevant 1^2S_1 levels (the Breit-Rabi diagram). The relevant good quantum numbers are M_J , the magnetic quantum number for the electron, and M_μ the muon spin magnetic quantum number.

The external magnetic field is in the opposite direction to the muon spin, so $M_\mu = -\frac{1}{2}$ and the states $(\frac{1}{2}, -\frac{1}{2})$ and $(-\frac{1}{2}, -\frac{1}{2})$ labelled respectively 2 and 3 are created in equal proportions. If these muonium atoms are left to decay, the decay positrons are emitted preferentially 'backwards'—opposed both to the muon beam direction and the external field direction. Resonant microwave fields induce transitions at frequencies ν_{12} and ν_{34} between states $2 \rightarrow 1$ and $3 \rightarrow 4$; the muon spin direction changes and the decay positrons are then emitted preferentially in the 'forward' direction of the external field. In other words, resonant transitions are detected by the change in the angular distribution of the decay positrons. Sets of proportional counters and scintillation counters are placed on both sides of the target in a 13.6 kG external magnetic field produced by a precision solenoid.

Caspersen *et al.* have measured ν_{12} and ν_{34} . Measurement of both eliminates the need for a separate NMR measurement of the muon magnetic moment with its associated uncertainties. The combination $(\nu_{12} + \nu_{34})$ is used to determine $\Delta\nu$ and $(\nu_{34} - \nu_{12})$ to determine the muon magnetic moment μ_μ in terms of the proton magnetic moment μ_p . Their results are $\Delta\nu = 4463 \pm 302.35 \pm (52)$ kHz (three or four times more precise than earlier measurements) and $(\mu_\mu/\mu_p) = 3.183 \pm 3403 \pm (44)$. This latter can be used to obtain a new, most precise value for the muon-electron mass ratio $(m_\mu/m_e) = 206.76859 \pm (29)$. The difference between the theoretical value for $\Delta\nu$ (Brodsky &

Fig. 1 Schematic diagram of Zeeman splitting of muonium hfs levels. At zero field, energy separation is $\Delta\nu$, the hfs interval.

Drell *A. Rev. nucl. Sci.* **20**, 147; 1970) and the new experimental value is 16.1 ± 6.6 kHz, 2.5 standard deviations of the combined error. The theoretical value is made up of several terms and the discrepancy may be due to an incomplete knowledge of the higher order radiative and recoil corrections to the bound state energy. These calculations are extremely complicated (for example Fulton & Repko *Phys. Rev. D* **14**, 1243; 1976). Weak interaction contributions such as neutral current effects are discounted by Caspersen *et al.* On the other hand, the measured density shifts of ν_{12} and ν_{34} indicate room for further experimental work. $\square$

Biological sun-traps

from J. Coombs

A European Seminar on Biological Solar Energy Conversion Systems was held in Grenoble-Autrains on 9–12 May, 1977. It was organised by Professor D. O. Hall, Kings College, University of London and Dr P. M. Vignais, CNRS, Grenoble, and sponsored by a number of French research agencies.

THE idea of solar energy has risen like the phoenix from the ashes of the world's fossil fuel reserves. The number of publications, reports and research proposals grows steadily, but how realistic are they? Some 300 scientists assembled at Autrans, under overcast skies and persistent drizzle to review the present state of the application of biological solar energy conversion.

The basic tenets remained unquestioned—that solar energy represents the only significant safe, renewable, non-polluting future source

J. Coombs is responsible for agricultural and biological research at the Philip Lyle Research Laboratory (Group Research and Development) Tate and Lyle Ltd, at the University of Reading.

of energy and chemical feed-stocks. Unlike the advocates of solar energy technology however, biologists suffer from the fact that much of the relevant work is not new, but really photosynthesis, farming and fermentation in another guise. Problems more often relate to application of existing knowledge than to innovation. This is reflected in proposals for the solar energy programme of the European Economic Community in which less than 15% of the expected budget is going to biological projects. Exceptions to this generality, where more basic research is needed, include the possible chemical control of photorespiration, dinitrogen fixation, microbial utilisation of highly lignified cellulose and photobiological production of hydrogen gas.

Reviews of current status of knowledge of photosynthesis (Y. de Kouchkovsky, CNRS, France) and crop systems (P. Chartier, INRA, France) served to define energy flows and metabolic pathways which could give a potential net harvest of about 6% of the 3.8×10^{21} J yr⁻¹ received from the Sun. This contrasts markedly with the total world estimate of 3×10^{21} J yr⁻¹ trapped in photosynthetic products. The energy recovered in useful agricultural produce is several orders of magnitude lower, and there is obvious scope for improvement. However, it was suggested (R. W. F. Hardy, E. I. DuPont de Nemours & Co., USA) that, in the short-term at least, attention to environmental factors, improved varieties, fertilisers and crop protection, coupled with changes in farming objectives—such as a reversal in the decline of high protein grain legume cultivation compared with low protein cereal grain production—will produce the greatest benefits.

With an increasing world population food production must remain the chief aim of agriculture. Plant products to be used for fuel or chemicals must therefore be derived either from agricultural wastes or from new cultural systems—preferably ones which do not encroach on existing agricultural land. Several approaches to this problem were presented.

It is clear that all agricultural systems produce waste, but fortunately not all on the scale described for salad production in France, where studies by J. M. Legarg and A. Buatois, (Université de Lyon) indicated that in some circumstances less than 10% of the produce is eaten. In general, however, reliable estimates of wastes are not available. Detailed surveys carried out by a team from Stanford Research Institute, USA (J. A. Alich *et al.*) in Sutter County, California indicated that (perhaps not surprisingly) manures

tended to be overestimated and forestry residues underestimated by as much as 30%. In this particular county the 16 million tons of low moisture field residues located could provide 2,050 million kilowatt hours of electricity or 13,300 million cubic feet of synthetic natural gas each year. In both cases these figures exceed the present consumption of energy in the given form. This conclusion does not take account of the fact that the bulk of such wastes may be profitably returned to the soil, and that collection may be difficult and costly. In general mill wood and bark residues seem to be most suitable for use as a fuel for process steam or electric power generation. Another important form of waste utilisation is treating straw with ammonia or alkali, a process which doubles the fodder energy value whilst considerably reducing the bulk (M. Israelsen, Biotechnisk Institut, Denmark).

Studies of the technical and economic feasibility of obtaining energy from crops in Australia (H. D. W. Saddler, Australian National University, Canberra), Silvicultural Biomass Plantations (R. E. Inman, The MITRE Corp., Virginia), and marine culture of giant kelp (H. A. Wilcox, Naval Underseas Center, San Diego, California) remain as paper studies, as a result of problems of economics, energy balance and technology. It was therefore refreshing to hear of the commercial production of *Spirulina* (H. Durand-Chastel, Sosa Texcoco, Mexico) and the potential for glycerol production from the alga *Dunaliella* (A. Ben-Amotz, Haifa, Israel), although these were small scale in comparison with the algal ponds used for sewage and waste disposal in the US as described by J. R. Benemann (University of California).

In spite of the lack of large-scale applications for immediate use, optimism was raised by the quality of much of the basic work reported. Here there was a definite emphasis on biological nitrogen fixation. R. A. Dixon (University of Sussex) indicated the possibilities of manipulating genetic information associated with symbiotic organisms, although the possibility of transferring the ability to fix nitrogen to non-legumes remains simply a speculation. The contribution of non-symbiotic nitrogen fixation and loose associations of bacteria with plants remains difficult to estimate. Using a field assay J. Balandreau and Y. Domergues (CNRS, Nancy) found less than 10 kg N ha⁻¹ yr⁻¹ being fixed in both African savannah and around maize plants. The elegant studies of K. E. Eriksson (Swedish Forest Products Research Laboratory, Stockholm) on enzyme mechanisms in-

involved in fungal degradation of lignocellulosic materials could be particularly important since at present no practical process exists for the production of glucose syrups from cellulose, the most abundant carbohydrate.

Hydrolysis, pyrolysis and fermentation of plant products give intermediates which can be converted to most of our present chemical feed-stocks using existing technology (P. Dupuy, INRA, Dijon). The impetus for implementing such technology will come as oil production peaks between 1980 and 1990. Production of ethanol as a fuel by fermentation of raw cane juice is already being investigated in Brazil. More exciting is the possibility of producing hydrogen gas by short-circuiting the photosynthetic process, using reconstituted systems produced by coupling of chloroplasts to hydrogenase as described by D. O. Hall. But both this system and synthetic photo-electric-chemical cells are a long way from practical realisation (A. San Pietro, Indiana).

Although nothing startling emerged from the meeting, a considerable change in the general attitude was noticeable. Proposals are becoming more rational and their limitations are being assessed more critically. The immediate effect may be to reduce waste of both energy and materials. In the longer term it is clear that new avenues of thought are being opened—discussions started during the conference continued unabated as the coaches returned us to the airports—and at last the Sun was shining. □

Magnetism in amorphous alloys

from F. E. Luborsky

An informal meeting on Magnetism in Amorphous Alloys was held on 6 May, 1977 at the University of Sussex, under the sponsorship of the Materials Science Division of the School of Engineering and Applied Sciences. It was organised by Dr A. W. Simpson (University of Sussex) and Professor E. P. Wohlfarth (Imperial College). Participants were invited from the chief European laboratories active in this field.

THERE has been intense research during the past few years on the ferromagnetic behaviour of certain alloys, especially those based on iron and nickel, which can be produced in the form of glassy

tapes by rapidly quenching from the melt. Several of these alloys have attractively high permeabilities and low magnetic losses and there is widespread interest in their possible applications as laminations in transformers and also in smaller electronic devices and in 'bubble memories'. Apart from this technological potential, the purely scientific questions raised by 'amorphous magnetism' have also attracted much attention.

What do we know about the origin of the magnetic properties of metallic alloys that are amorphous? What are the significant unanswered questions related to amorphous magnetism? What is the potential for application of these new transition metal amorphous alloys? These were some of the questions which the Sussex meeting hoped to answer.

In the only formal lecture of the day E. P. Wohlfarth introduced the subject, discussing why interest has arisen in the magnetic properties of the metal-metalloid amorphous alloys, which show soft magnetic properties with applications in transformers, inductors and magnetic sensors. He also discussed what the magnetic properties can tell us about the structure; the reawakened interest in itinerant compared with localised models of magnetism; and finally the origin of the magnetic properties of technological interest.

During the lecture and the discussions which took up the rest of the day many interesting ideas emerged, a few of which are summarised here.

It now seems clear that the non-crystallinity influences the primary magnetic properties in relatively small ways as the result of the variance, or distribution, in the exchange integral. This may be observed directly, for example, in the distribution of hyperfine fields obtained from Mössbauer spectroscopy. However the critical indices of crystalline and amorphous alloys are essentially the same. The relatively large differences in saturation magnetisation and Curie temperature between crystalline and amorphous alloys occurs because of the presence of the metalloid, which is necessary to stabilise the amorphous phase, and not because of the lack of crystalline order.

It was pointed out that very little is known about the effect of preparation variables (quench rate, melt temperature, annealing) on the variance of the exchange integral. The itinerant electron model, as for conventional crystalline alloys, provides a better description of the primary magnetic properties of amorphous alloys than the localised model. There is a smoothing out of the density of states curve for amorphous alloys but since the Fermi level is near the middle of the band, nothing much

will happen to the magnetic moment.

Factors which contribute towards making good soft magnetic materials include primary properties such as moment and Curie temperature, as well as the secondary properties such as the various anisotropies present, magnetostriction and inhomogeneities. The effect of preparation conditions and subsequent mechanical treatment and heat treatment on these secondary properties is particularly important. There are basically three sources of anisotropy: stress-magnetostriction, dipole effects arising for example from inhomogeneities in M_s or from directional atomic pairing, and spin-orbit coupling. The stress-magnetostriction interaction anisotropy is well understood from the many years of work with conventional crystalline alloys. For the amorphous alloys, the stress is understood to develop during the rapid solidification or during subsequent handling, but a fundamental description of magnetostriction and the effect of the non-crystalline structure on magnetostriction are both lacking. The presence of directional atomic order

arising from transition metal atom pairs and metalloid interstitial ordering has been shown to be the dominant source of anisotropy after annealing to minimise or remove the stress-induced magnetostrictive anisotropy. Thus the secondary magnetic properties are controlled by the same kinds of anisotropy as in crystalline alloys, but the magnetocrystalline anisotropy is minimal in a wide range of transition metal-metalloid amorphous compositions. This results in a wide range of compositions, with a range of magnetisations and other properties, of significant technological potential.

Wohlfarth summarised prospects in the near future for transition metal-metalloid amorphous alloys by suggesting that in the next few years there will be more theoretical work on the itinerant and localised models, there will be more relevant measurements on a variety of alloys, and new useful soft magnetic alloys will be developed.

F. E. Luborsky is with the R&D Center of General Electric, Schenectady, New York, and currently at the University of Sussex.

A hundred years ago

THE *Turkestan Gazette* gives the latest news from M. Prshevsky, dated from Lob Nor, February 22. After having reached this lake by the valley of the Lower Tarim, M. Prshevsky advanced 130 miles east of the lake. The survey and the astronomical measurements of latitudes and longitudes he has made give a totally new aspect to the map of the country. The population on the banks of the Tarim and around the Lob Nor is very sparse; the people speak almost the same language as that of Eastern Turkestan. The flora and fauna of the locality are very poor; some vegetation is found only in the Tarim valley, the neighbourhood being a true desert. During February and March M. Prshevsky was to stay in the Lower Tarim, during May at Yuldus, and during June at Kunghes. About the beginning of July he proposes to return to Kuldsha to begin in August his journey to the Tibet.

A RUSSIAN work, by M. Bogolubsky, on Gold and Gold Mining in Russia, is worthy of notice. It contains very interesting information upon that industry in Russia and Siberia. We observe that the area of gold mines occupies in the Russian empire about

2,100,000 square miles, and now yields yearly about 80,000 lbs of gold, in value upwards of 3,000,000 sterling. The total amount of gold produced in Russia since 1752 has been upwards of 2,500,000 lbs.

MUSCULAR contraction, it is known, is always accompanied with electric phenomena; the difference of electric potential between two points of a muscle, undergoes a diminution, which according to Bernstein, proceeds by about 1/100 of a second the contraction of the muscle. This *electric variation* has been observed in various muscles, and in particular on the heart (by Du Bois Reymond and Kühne), and recently M. Marey has represented it graphically by photographing the indications of a Lippman capillary electrometer. We learn from the *Journal de Physique*, that M. De la Roche has tried the experiment on the heart of a living man. Two points of the epidermis of the chest were connected with the poles of a capillary electrometer, by means of electrodes, formed each of a bar of amalgamated zinc with a plug of muslin at its lower end saturated with sulphate of zinc. Held with insulating handles, the bars were applied, one with its plug opposite the point of the heart, under the left nipple, and the other to another point of the chest. The mercurial column was then seen to execute a series of very distinct periodical pulsations synchronous with the pulse; each pulsation even marked the double movement of the heart (of the auricles and ventricles). The amplitude corresponded to about 1/1000 Daniell.

Dynamics of folded proteins

J. Andrew McCammon, Bruce R. Gelin & Martin Karplus

Department of Chemistry, Harvard University, Cambridge, Massachusetts 02138

The dynamics of a folded globular protein (bovine pancreatic trypsin inhibitor) have been studied by solving the equations of motion for the atoms with an empirical potential energy function. The results provide the magnitude, correlations and decay of fluctuations about the average structure. These suggest that the protein interior is fluid-like in that the local atom motions have a diffusional character.

RESULTS of X-ray crystallography provide a picture of a globular protein in its native conformation as a well defined, densely-packed structure. Other experimental data¹⁻¹⁰ and theoretical considerations¹¹⁻¹³ indicate that there is considerable local motion inside a protein at ordinary temperatures. Moreover, the structural data themselves show that significant residue or subunit displacements have an important role in the activity of proteins (for example, enzyme catalysis¹⁴, haemoglobin cooperativity¹⁵, immunoglobulin action¹⁶). To obtain a more complete understanding of proteins, it is essential to have a detailed knowledge of their dynamics. In spite of the considerable effort directed toward protein folding¹⁷, very little has been done to investigate the motions of a protein in the neighbourhood of its equilibrium configuration. For certain cases in which the displacements along a suitably chosen co-ordinate can be isolated (for example, aromatic side chain rotations in the pancreatic trypsin inhibitor¹⁸, the opening and closing of the active site cleft in lysozyme¹⁹), it has been demonstrated that empirical energy functions can be used to analyse the motion involved. Here we undertake a more general examination of the internal dynamics of a folded globular protein. The approach used is of the molecular dynamics type¹⁹. In such a study the classical equations of motion for all the atoms of an assembly are solved simultaneously for a suitable time period and detailed information is extracted by analysing the resulting atomic trajectories. The full interatomic potential can be used to obtain the forces on the atoms, so that the method is applicable even when the system is highly anharmonic. The molecular dynamics approach has been very successful in revealing structural and dynamical characteristics of fluids¹⁹. As we demonstrate in what follows, molecular dynamics can have a corresponding role for the internal motions of proteins.

Bovine pancreatic trypsin inhibitor (PTI) (see Fig. 1a) was selected for study because of its small size (58 amino acid residues), high stability and accurately determined X-ray structure^{20,21}. Four water molecules, which are strongly bound in the interior, were included in the dynamical simulation. The potential energy was represented by an empirical function¹⁸ composed of a sum of terms associated with bond lengths, bond angles, dihedral angles, hydrogen bonds, and non-bonded (van der Waals and electrostatic) interactions. Hydrogen atoms are not explicitly considered, but are combined with the heavy atoms to which they are bonded by a suitable adjustment of atomic parameters. This use of 'extended atoms' reduces the

number of interactions which must be calculated and also permits larger steps in the trajectory calculation since the high frequency hydrogen vibrations have been eliminated. Integration of the equations of motion was performed by means of the Gear algorithm²² with time steps of 9.78×10^{-16} s. X-ray coordinates²¹ were used for the initial positions and the initial velocities were set equal to zero. After 100 equilibration steps, the stresses in the initial structure had partly relaxed and the system had an internal kinetic energy corresponding to a temperature of 140 K. At this point, all velocities were multiplied by a factor of 1.5 and 250 more equilibration steps were taken. The added kinetic energy ($250.6 \text{ kcal mol}^{-1}$) partitioned itself between kinetic and potential terms during this interval, and an average kinetic temperature of 285 K was reached. The actual simulation consisted of 9,000 additional steps, corresponding to 8.8 ps. Some equilibration of the bond lengths, bond angles and electrostatic interactions continues during the first 3 ps of the simulation, producing a small rise in temperature. Over the whole simulation, the average temperature is 295 K and the total energy is well conserved, changing by only $0.7 \text{ kcal mol}^{-1}$.

In what follows we first describe results concerned with the relation between the time-averaged and X-ray structures and with the magnitudes of structural fluctuations. We then examine the details of the dynamics, the correlation and damping of fluctuations, and some examples of the larger changes that occur. Of primary importance are the conclusions reached concerning the fluid-like nature of the internal motions, which will clearly have to be considered in developing dynamical models for biological processes.

Time-averaged structure and fluctuations

The time-averaged structure obtained in the dynamics run is near the X-ray structure but not identical with it; the root mean square (r.m.s.) deviation of the α carbons is 1.2 Å and that for all the atoms is 1.7 Å. The largest deviations come from the two ends of the molecule, the external loop (residues 25-28) and exposed sidechains. The two parts of the β sheet (residues 18-24, 29-35) and the α helix (residues 47-56) have significantly smaller deviations.

Use of the X-ray structure as the starting configuration corresponds to $0.4 \text{ kcal mol}^{-1}$ of kinetic energy per atom after equilibration (140 K); for the main dynamics run (295 K), the mean kinetic energy per atom is about $0.9 \text{ kcal mol}^{-1}$. Although there is no tendency to unfold, the dynamic development with this kinetic energy permits the molecule to make small rearrangements throughout; a picture of the structure after 3.2 ps is shown in Fig. 1b. Apparently the PTI molecule samples a series of neighbouring conformations, the average of which is not identical with the X-ray structure. It is not clear how much of the difference is a real effect (in the sense that the structure in the crystal is constrained) and how much is due to inaccuracies in the potential function and the absence of solvent. In lysozyme, comparison of the X-ray structures for the triclinic and tetragonal crystal forms^{23,24} shows an r.m.s.

Fig. 1 The peptide backbone (α carbons) and disulphide bonds of PTI. *a*, X-ray structure²¹. *b*, Time evolved structure after 3.2 ps of dynamical simulation.

deviation of backbone atoms equal to 0.5 Å, with the largest changes at the surface of the protein. Also, a variety of other studies^{25–27} support the picture of a protein accommodating its structure to different environments. In any case, the X-ray and dynamic average structures are sufficiently similar that the present results should give a meaningful approximation to the short-time dynamics of PTI.

Figure 2 shows the r.m.s. displacements of the α carbons, relative to the dynamical average structure. The three residues at the carboxyl end of the chain have particularly large fluctuations; these are due to the presence of excess kinetic energy resulting from local strain in the initial structure. Some of this kinetic energy was transferred to the nearby amino end of the chain, which also exhibits relatively large r.m.s. displacements. The important fluctuations in residues 25–28 of the loop connecting the two strands of β sheet seem to reflect an intrinsic softness in this part of the molecule. The smaller fluctuations of the β sheet and α helical regions are also evident. The side-chain atom displacements are somewhat larger than those of the α carbons, but generally show a similar pattern of variation. The average r.m.s. fluctuation of all atoms is 0.9 Å. Particularly large r.m.s. displacements (1.8–3.1 Å) occur in the side-chains of Lys 26, Arg 39, Arg 42, Lys 46 and Met 52; all of these are at the surface of the protein. Overall, the large fluctuation regions correspond to those deviating most from the X-ray structure. In principle, the temperature factors from the X-ray analysis can be compared with the calculated fluctuations. The r.m.s. atomic fluctuation for the α carbons

obtained from the experimental temperature factor is 0.4 Å. Also, some of the more mobile regions correspond to groups of atoms which were not located or had unusually high temperature factors (J. Deisenhofer, personal communication).

The range of variation of the internal coordinates in the static structure can be compared with the dynamical averages and fluctuations. Since the X-ray results for bond lengths and angles correspond to standard values for the different amino acids²¹, we use for comparison the energy-refined geometry (ERG)¹⁸, which reflects the effect of the environment on the coordinates. Selected examples for backbone coordinates are listed in Table 1. It can be seen that the ERG and dynamical averages and r.m.s. variations are in close correspondence. It should also be noted that the average r.m.s. dynamical fluctuation of any given coordinate is two to five times larger than the variation in the coordinate throughout the molecule. The results for the side chains are similar. For the dihedral angle ω , neither the ERG refinement nor the dynamic results show any significant distortions or unusual fluctuations for residues 14–17; this differs from the X-ray results²¹.

The dynamic averages for individual ϕ and ψ dihedral angles differ from the corresponding ERG results by less than 15° for 70 of the 115 backbone angles and by somewhat larger values for the rest (up to 30°). The behaviour of the sidechain dihedral angles is similar to ϕ and ψ .

The r.m.s. dynamic fluctuations of the bond lengths, the bond angles, and the ω angles are essentially constant along the backbone except for slightly (~20%) larger fluctuations in

Fig. 2 R.m.s. displacements (—) and maximum displacements (....) of the α carbons, relative to the dynamical average structure.

residues 56–58. For the ϕ and ψ dihedral angles, the r.m.s. dynamic fluctuations range from 10° to 40° and show more variation along the chain; in both the β sheet and α helix regions these fluctuations are about 18° on the average, while in the loop region the fluctuations average about 25° .

Bond lengths calculated from the dynamically averaged set of Cartesian coordinates were uniformly 0.02–0.03 Å shorter than the average bond lengths obtained directly. A similar discrepancy arises in calculating interatomic distances from X-ray diffraction data because of thermal atomic motion²⁸.

Time-dependence of motions

The fact that the individual PTI internal coordinates exhibit dynamic fluctuations of appreciable magnitude raises questions concerning the details of the motions, including their time evolution and spatial correlation.

To illustrate the time-dependence of individual coordinate fluctuations, we present results obtained for the Phe 22. This residue is relatively well buried in the protein and so should exemplify the effect of interactions between different parts of the molecule; other residues examined were found to have qualitatively similar dynamic behaviour. Figure 3a shows the time-dependence of several Phe 22 internal coordinates; the considerable variation in the frequencies, magnitudes of fluctuations, and irregularities of the behaviour of the different coordinates is evident.

To quantitate the average decay characteristics of fluctuations, so as to best analyse the coupling between the coordinate and the rest of the molecule, it is helpful to introduce time

correlation functions²⁹. The time correlation function $C_A(t) = \langle A(\tau+t)A(\tau) \rangle$, for a dynamical variable A is obtained by multiplying the value of $A(\tau)$ by $A(\tau+t)$, the value taken by A after the system has evolved for an additional time t , calculating such products for a representative set of initial times τ and averaging. If A is the fluctuation of a variable from its mean value, $\langle [A(\tau)]^2 \rangle$ is the mean-square fluctuation of the variable for an equilibrated system, while the time correlation function $C_A(t)$ describes the average decay behaviour of the fluctuation. Time correlation functions for the fluctuations of the internal coordinates of Phe 22 shown in Fig. 3a are given in Fig. 3b. Fluctuations of the backbone bond length $N_{22}-C_{22}^{\alpha}$ exhibit a partial loss of correlation in the first 0.1 ps, followed by a very slow decay of the residual small amplitude oscillation. Other backbone and sidechain bond lengths behave similarly. Although the specific oscillation frequencies depend on the force constants and the masses of the bonded atoms, all have long-lived oscillations; among others, the disulphide bond $S_{14}-S_{38}$ was examined and showed no atypical features. The other stiff internal coordinates (bond angles, dihedral angle ω) also exhibit partial loss of correlation in the first 0.1 ps but have persistent though less regular small-amplitude oscillation at longer times.

The relaxation behaviour can be analysed further by obtaining the Fourier transform of the correlation function and finding the dominant frequency components. For the $N_{22}-C_{22}^{\alpha}$ bond, the main peaks are found at 800 cm^{-1} , $1,010\text{ cm}^{-1}$, $1,110\text{ cm}^{-1}$, $1,170\text{ cm}^{-1}$, and $1,430\text{ cm}^{-1}$. These frequencies correspond to the calculated normal modes that involve the largest displacements of the $N-C^{\alpha}$ bond length of the isolated fragment $\text{CH}_3\text{-CO-Phe-NH-CH}_3$ ($787; 952; 1,099; 1,161$; and $1,425\text{ cm}^{-1}$). In addition, there are relatively small contributions from many low frequency motions. Thus, the $N_{22}-C_{22}^{\alpha}$ bond fluctuations are those expected for a strongly coupled system of local oscillators that is weakly coupled to the rest of the protein molecule. For the bond angles and the dihedral angle ω , there are important frequency contributions in the range $300\text{--}1,200\text{ cm}^{-1}$, which correspond to the fragment vibration frequencies associated with these degrees of freedom. Since frequencies below 300 cm^{-1} are also important, it seems that the bond angle and the dihedral angle ω fluctuations are significantly coupled to the protein matrix. Backbone dihedral angles (ϕ, ψ) are seen in Fig. 3b to exhibit considerable damping, though ϕ_{22} preserves long term correlation in a low frequency oscillation of the order of 2 ps. For the sidechain dihedral angle, χ_{22}^2 , associated with the rotation of the phenyl ring, damping produces a nearly monotonic decay with a relaxation time of 0.2 ps. It is clear from the decay behaviour of the correlation functions that the fluctuations of the ϕ, ψ and χ dihedral angles are dominated by interactions with the protein matrix. It is reasonable that torsional motions which involve substantial displacements of large groups inside proteins

Table 1 Backbone internal coordinates*

* Units are Å for bond lengths, degrees for bond and dihedral angles.

† These values represent the average and r.m.s. variation over the 58 amino acids of a given type of coordinate.

‡ These values represent the r.m.s. dynamical fluctuation of the individual coordinate averaged over the 58 amino acids.

(for example, aromatic sidechains) will have a collective, diffusion-like behaviour, while those subject to smaller steric interactions will retain more of a local character.

The relaxation of individual atom fluctuations seems to be dominated by rotations of the dihedral angles. Atom displacement time correlation functions exhibit qualitative features and characteristic times similar to those shown for the dihedral angles. In many cases, the correlation functions show nearly monotonic decay with relaxation times of the order of a ps.

Correlated fluctuations

The large fluctuations found in the individual dihedral angles might seem to suggest a degree of structural mobility that is greater than that corresponding to the r.m.s. fluctuations of the individual atoms. In fact, the fluctuations of neighbouring dihedral angles are generally correlated so as to minimise disturbances of the backbone and sidechain atoms. For the typical backbone dihedral angle ϕ_{33} , which is at the centre of a strand of β sheet, the observed equal-time correlations of fluctuations of neighbouring ϕ angles and of neighbouring ψ angles are shown in Fig. 4. The large negative correlation $\langle \Delta\phi_{33}(\tau)\Delta\psi_{32}(\tau) \rangle$ is striking and has as a consequence the conservation of the general direction of the backbone and of the approximate position of the sidechains; the larger the individual dihedral fluctuations, the stronger the anti-correlation $\langle \Delta\phi_i(\tau)\Delta\psi_{i-1}(\tau) \rangle$ is found to be. The correlation pattern seen in Fig. 4 is similar to that obtained for an isolated harmonic α helix³⁰. A corresponding pattern of positive and negative dihedral angle correlations is likely to occur generally in strongly conserved regions of secondary structure. The anti-correlation $\langle \Delta\phi_i(\tau)\Delta\psi_{i-1}(\tau) \rangle$ is, in fact, present in other parts of the protein, though somewhat weaker outside the β sheet and α helical regions.

Structure-conserving correlations between dihedral angles also exist in the sidechains. For the eight aromatic sidechains with dihedral angles χ^1 and χ^2 , the normalised correlations $\langle \Delta\chi^1\Delta\chi^2 \rangle / \langle (\Delta\chi^1)^2 \rangle^{1/2} \langle (\Delta\chi^2)^2 \rangle^{1/2}$ range from -0.05 to -0.63; again, dihedral angles with larger r.m.s. fluctuations tend to be more strongly anti-correlated. This correlation is the one required to conserve approximately the orientation of the aromatic rings with respect to the polypeptide backbone.

Concerted motions

In addition to the structure-preserving correlations, a number of concerted atom motions were observed. One of these involves the relatively flexible loop region (residues 25-29) which seems to oscillate as a whole with a period of approximately 6 ps, as well as undergoing changes in shape (see Fig. 1a, b). Some damping of this motion would be expected in solution due to the high solvent accessibility of the loop.

Time correlation functions involving different internal coordinates (for example, $\langle A(\tau+t)B(\tau) \rangle$) can be used to probe the dynamical character of non-local, collective motions in the protein. One such case concerns time correlations between the fluctuations of the dihedral angle ϕ_{33} in the β sheet and the fluctuations of other backbone and sidechain dihedral angles in the molecule. The results show that both strands of the β sheet and some additional residues participate in a low-frequency 'rippling motion' ($\nu = 15 \text{ cm}^{-1}$); within each strand of the β sheet, backbone dihedral angles tend to oscillate with the phase relationships suggested by Fig. 4. Examination of the correlation functions for the atoms involved also shows damped oscillations of the same frequency.

A feature of the dynamics is that certain groups in the molecule undergo transitions from one minimum to another. Such behaviour was found for a number of sidechains;

Fig. 3 a, Time development of selected Phe 22 internal coordinates; the initial time is 4.9 ps after the beginning of the dynamical simulation; average values are indicated by broken line segments. b, Time correlation functions for fluctuations of selected Phe 22 internal coordinates.

Fig. 4 Normalised equal-time correlations of fluctuations in ϕ_{33} with fluctuations in ϕ_{33+k} (—) and with fluctuations in ψ_{33+k} (---); the quantities plotted are, for example, $\langle \Delta\phi_{33}\Delta\phi_{33+k} \rangle / \langle (\Delta\phi_{33})^2 \rangle^{1/2} \langle (\Delta\phi_{33+k})^2 \rangle^{1/2}$.

for example, Met 52, where χ_{52}^2 moved successively from $-60^\circ \rightarrow +60^\circ \rightarrow -60^\circ \rightarrow 180^\circ \rightarrow 60^\circ \rightarrow 180^\circ$ and Arg 39, where χ_{39}^2 moved successively from $-60^\circ \rightarrow 180^\circ \rightarrow 60^\circ$. The times involved in these rotations vary between 0.2 and 2 ps. Since these sidechains are on the surface of the molecule, they have low barriers due to the protein; their detailed dynamics would be expected to be altered by interactions with the solvent.

In addition to the sidechain reorientations, there occurred a few concerted transitions in the backbone involving ψ_{i-1} , ϕ_i dihedral angle pairs. In these transitions, the anti-correlated angles ψ_{i-1} and ϕ_i rotate in the opposite sense by about 180° so that the intervening amide group flips over, but the backbone and sidechain directions are only slightly altered. The pairs involved are ψ_{38} , ϕ_{39} (near the 14–38 disulphide bond); ψ_{44} , ϕ_{45} ; and ψ_{56} , ϕ_{57} . All of these amide groups are located near the surface of the protein, so that the probability and dynamics of their transitions could be affected by solvent. Nevertheless, it is worthwhile to examine the behaviour since it can serve as a model of structural alterations in the presence of the protein matrix. Figure 5 shows the results for the ψ_{38} , ϕ_{39} pair. The transition is seen to take place in about 1 ps. During this period, the variation in the angles is roughly linear in time and the kinetic energy of the amide group does not show any significant departure from the thermal value. The amide flip is seen to be followed by a conformational adjustment period of 3–4 ps, during which ψ_{38} , ϕ_{39} drift over a relatively small angular interval into their new equilibrium ranges. It is apparent that there is a smooth change from one minimum to the other, while the protein relaxes so that the transition can occur without a large activation energy. The details of the driving torques and other matrix effects remain to be analysed, as do a variety of other larger scale motions that occur.

Fig. 5 Amide group transition; the time development of ψ_{38} and ϕ_{39} during the transition is shown.

Discussion

A molecular dynamics study of the pancreatic trypsin inhibitor has revealed a rich variety of motional phenomena that occur on the atomic level at ordinary temperatures. PTI has been shown to exhibit significant structural fluctuations, and detailed information on the magnitude, correlations and decay of these fluctuations has been obtained.

One important result of the dynamical simulation is that many aspects of the internal motion of PTI suggest that the folded protein is fluid-like at ordinary temperatures³¹. By this we mean that the fluctuations in atom positions, although confined to the neighbourhood of the average structure, have a diffusional character. In other words, the dynamics of atomic displacements are dominated by collisions with neighbouring atoms, at least on the picosecond time scale.

Also of significance is the heat capacity of the protein, which may be calculated from the magnitude of fluctuations in the kinetic energy³². Over the final 2 ps of the simulation, these fluctuations had the average value $\langle (\Delta KE)^2 \rangle = 87 \text{ kcal}^2 \text{ mol}^{-2}$; the corresponding heat capacity per atom is $C = 2.3 k$, where k is Boltzmann's constant. This result, which is midway between those expected for a harmonic solid ($C = 3k$) and for a hard-sphere fluid ($C = 1.5k$) indicates that the potential governing the atomic motions is significantly anharmonic. Similar values have been measured in real fluids; for example, at 84 K in liquid argon, $C = 2.32k$ (ref. 33). The calculated heat capacity of $0.33 \text{ cal g}^{-1} \text{ K}^{-1}$ is consistent with experimental values for proteins¹³.

An idealised model for proteins is that of a dense hard-sphere fluid composed of particles that are connected by flexible links. This implies that many of the dynamical properties (though not necessarily the correct average structure) can be obtained from any potential function which includes the forces that depend strongly on distance (covalent and hydrogen bonds, non-bonded repulsions) and provides sufficient attractive interactions to preserve the compact structure of the native system. Such a representation of a protein has much in common with the hard-sphere model of dense fluids, which has had considerable success recently in reproducing their equilibrium and dynamic properties³⁴. The close correspondence of the protein dynamics with that of the high temperature (300 K) solid phase of normal alkanes is also of interest^{35,36}. The importance of motions in which hard-sphere interactions dominate suggests that in conformational changes the non-bonded contacts will determine the transmission of effects from one part of the molecule to another. One such case of biological interest is the recent determination of the mechanism of tertiary structural change in a haemoglobin subunit, where non-bonded contacts were found to have the dominant role³⁷.

Although the time scale of the simulation is rather short, it provides essential details concerning the dynamics that should be of considerable utility in analysing longer time scale phenomena. A basic result is the r.m.s. atom fluctuation of $0.9 \text{ \AA}$. In a stochastic model that assumes independent atom motions, this provides a means for estimating the probability of larger fluctuations. Of corresponding significance is the nearly monotonic decay of the atom fluctuations with a time constant of $\sim 1 \text{ ps}$. It is also of interest that the kinetic energy of residues 49–58 remains 10–20% above the equipartition value for more than 9 ps; this indicates that vibrational energy can localise for relatively long time periods in proteins; this may be compared with the vibrational relaxation times in polyatomic fluids, which are often of the order of many picoseconds, even when efficient relaxation pathways exist³⁸.

It is clear from the dynamic simulation that the protein with room temperature kinetic energy samples highly anharmonic regions of the potential surface. Further, from an examination of the details of the coordinates during the run, as well as the dynamic average structure, it follows that the protein is able to wander over a range of conformations that are in the neighbourhood of the X-ray structure but not identical with it. The protein

seems to be oscillating in a confined multidimensional space, as shown by the fact that the fluctuations from the average structure are similar during the entire dynamical run. Some of the fluctuations that involve reorientation of sidechains or localised portions of the backbone may represent local minima, though their detailed characteristics have not yet been investigated.

Two limitations of the present model need to be mentioned. First is the approximate nature of the potential energy function. Although in previous applications this function has proved reliable for energy refinement of the PTI structure and the calculation of vibrational spectra of small peptides, some of the details of dynamical simulations of proteins may be sensitive to the choice of potentials. Also, hydrogen atoms have not been explicitly included in the simulation. Their characteristically high frequency motions suggest that replacing them by what can be regarded as an effectively averaged potential may not be a severe approximation; nevertheless, there remains a question as to whether their detailed consideration could introduce somewhat more rigidity into the close-packed structure.

Another limitation of the model is the neglect of solvent. The structure and dynamics of groups at the protein surface are expected to be influenced by hydrogen-bond formation and collisions with solvent molecules, as well as by hydrophobic effects that vary with the exposed area. But, many of the essential features of the internal motions analysed in the dynamic simulation of PTI are not expected to be grossly altered by the presence of solvent. The electrostatic component of the potential energy was found to vary over a smaller range than some other energy components during most of the run, and there was no marked low-frequency alteration of the overall shape of the protein during the simulation. Large variations in these properties, which might be found on a longer time scale, would require consideration of dielectric and hydrodynamic effects, respectively.

It is most important to have available detailed tests of the dynamic simulation. Most closely related are results obtained from fluorescence depolarisation, NMR, fluorescence quenching and hydrogen exchange studies. Measurements of fluorescence depolarisation on a picosecond time scale could be interpreted directly by use of the dynamic results. Other data (for example, fluorescence quenching) require assumptions, such as that of stochastic behaviour, to use the information on fluctuations that has been obtained. For certain rare phenomena that are not represented in the dynamic simulation because they involve high activation barriers (for example, rotation of a tyrosine

sidechain), special methods based on dynamics starting at the transition state may have to be introduced^{39,40}. Comparisons with a variety of experimental data, as well as studies of motional effects on enzyme mechanisms and of conformational changes involved in ligand binding are in progress. A combination of these theoretical approaches with the interpretation of related experiments will provide a unified description of motions in proteins.

We thank J. Deisenhofer and W. Steigemann for the PTI coordinates and John Deutch, Peter Wolynes, Peter Rossky, Stephen Harrison and Aneesur Rahman for helpful discussions. We thank Dr Carl Moser and CECAM for the hospitality extended to us at a summer workshop (1976) during which the initial calculations were done. The work was supported by the US NSF and NIH.

The rings of Uranus: theory

S. F. Dermott & T. Gold

Center for Radiophysics and Space Research, Space Sciences Building, Cornell University, Ithaca, New York 14853

The structure of the recently discovered rings of Uranus is accounted for by a series of orbital resonances with the satellites Ariel, Titania and Oberon. The observations and their interpretation will considerably improve our knowledge of the mass of the planet and its dynamical oblateness and could influence our ideas on the formation of planets and satellites.

THE recently discovered rings encircling the planet Uranus¹ are the second example we have of a planetary ring system; however, the rings of Saturn and those of Uranus have quite different structures, and different theoretical discussions will be required. In each case resonant interactions, between the particles making up the rings and the perturb-

ing satellites, have to be considered. But in the case of Saturn the rings are wide, and a continuum of orbital periods of the circulating particles exists; the sharply defined orbits for which resonance effects with the satellites can be invoked concern the divisions between the rings. One has to suppose then that a profuse supply of particulate matter was available to populate a disk surrounding the planet, and that orbit-orbit resonances involving particles and satellites have caused certain lanes to be swept clear. In the case of the Uranus ring system the situation is in a sense the opposite: the rings themselves are exceedingly narrow and resonances can therefore not be responsible for defining them by any sweeping action. A set of rings 10 km wide with a radius of the order of 45,000 km must be defined by conditions that lend a stability peculiar to the ring

orbits alone. Resonances with satellites must provide here the explanation for the presence or great concentration of the orbiting material in exceedingly narrow lanes.

An explanation in terms of celestial mechanics of any observed orbit-orbit resonance must have two components: one is the stability of the motion maintaining the precise relationship of periods that is seen; the other is a mechanism for setting up the particular resonance. If only gravitational forces are invoked the system is strictly conservative and the precise condition of a resonance cannot be expected to be reached. Liouville's theorem applies and material cannot become concentrated in the particular domain of phase space represented by a resonance. For this reason other orbital resonances in the Solar System have had explanations involving the operation of slight but significant non-conservative forces, namely the tidal drag between a satellite and its parent planet. It is the secular changes resulting from the drag-forces that drive the system through the various numerical relationships, with the possibility then of being arrested in one of them. The requirement is for the presence of a drag-force small enough so that the slight effects of a resonance can arrest the secular evolution, yet large enough to drive it through some resonance conditions in the time available. It is the lengths of the time-spans that have been available in the solar system that have made it possible for so many systems to be channelled into resonances.

In the case of particles, tidal forces are negligibly small, and another drag force is required. The case that the Poynting-Robertson effect (light-drag) on small particles will feed them into resonant orbits has been discussed before² and seems applicable to the case of Uranus' rings. We thus envisage a supply of small particles having been available in the neighbourhood of Uranus, and the action of the Poynting-Robertson drag (chiefly due to sunlight) having been responsible for driving them gradually, on spiralling orbits, towards the planet. It is understood that such a swarm would settle down, through internal friction, to a common plane, and that this plane would adjust itself to coincide with the equatorial plane of an oblate planet. In the course of this slow spiralling, resonances with the satellites of Uranus will be encountered. At such resonances, when certain precise numerical relations hold between the mean periods of the satellites and of the particles in the disk, it is possible for angular momentum to be transferred between them. A stable condition can then occur when the angular momentum that a particle loses by the Poynting-Robertson effect is just compensated by the angular momentum supplied by the satellites in the resonance.

The search for the appropriate resonances accounting for the rings of Uranus was guided by the following considerations. First, the orbits of the particles slowly spiralling towards Uranus will be closely circular and will lie in the equatorial plane of the planet. The satellites of

Fig. 1 Libration of the ring particles about a stable longitude is expected, and this would produce a longitudinal dependence of the ring's opacity. The arrows mark the paths of the librating particles in a coordinate frame centred on the planet but rotating with the resonant mean motion. The straight lines represent arbitrary apparent paths of the occulting star projected onto the orbital plane of the particles. The fact that each ring is caught in a different phase at the occultation will account for some being seen on one side of the planet only and some on both.

Uranus also have orbits that are nearly circular and in the equatorial plane (with the exception of the tiny Miranda³). In such circumstances resonance between two bodies has no dynamical significance. This is because in a circular, coplanar system of orbits there are no reference points (apses or nodes), and thus all orbital configurations are equally stable and the system is degenerate. Resonances involving three bodies—a ring particle and two satellites—do not have this degeneracy as one of the satellites can act as a reference point for the other two. In effect, the satellite takes over the role that an apse or a node has in two-body resonance. The precise condition for three-body resonance is

$$qn_1 - (q+p)n_2 + pn_3 = 0 \quad (1)$$

where the n_i are mean motions (suffix 1 refers to the ring particle) and p and q are integers. It follows from equation (1) that in a reference frame rotating with the mean motion of the ring particle, the mean motions of the satellites are commensurate in the ratio $p : (p+q)$.

The strength of such resonances, that is, for our purposes, the amount of angular momentum that can be transferred to the ring particle, is known to depend chiefly on: the order of the resonance, q , (which must be low and preferably unity); the product of the satellite masses; and on a certain function of their orbital radii^{4,5}. From estimates of the function masses based on their visual magnitudes⁶ one would suppose that the combinations of Ariel and Titania and of Ariel and Oberon would dominate (see Table 1). Discounting the tiny Miranda, Ariel is the satellite closest to Uranus.

In comparing the observational data on the rings with predictions based on resonance theory, we consider that the outer two obscuring events, one seen on one side of the planet and one at a different distance on the other, are two separate rings. As the particles in a resonant ring are expected to be librating about a stable longitude (displaced from the longitude of conjunction of the perturbing satellites by an angle dependent on the mean torque that needs to be supplied by the resonance to offset the light drag), the particle distribution in the ring will

Table 1 Products of satellite masses

Satellites	$m_2 m_3$ (Planetary units $\times 10^{-11}$)
Miranda, Ariel	19
Miranda, Umbriel	5
Miranda, Titania	32
Miranda, Oberon	25
Ariel, Umbriel	99
Ariel, Titania	580
Ariel, Oberon	447
Umbriel, Titania	170
Umbriel, Oberon	131
Titania, Oberon	770

have a strong longitudinal dependence (see Fig. 1). In such circumstances, the characteristics of the obscuring events will depend on the phase in which each ring is caught by the occultation. It is only at the time of conjunction of the pair of satellites responsible for a set of rings that these would have a common orientation. Thus, one particular path could produce two narrow events of similar opacity, but a path passing near the centre of libration could produce a broader and more intense event on one side of the planet (possibly even with a double peak, as observed for the outer two rings) and nothing at all on the other. We thus have to account for six rings, whose radii have the distinctive pattern of three pairs.

The two sets of preliminary estimates of the radii of the six rings, as calculated by Elliot *et al.*¹ and Marsden⁷, and the radii of the resonant orbits for the dynamically more significant pairs of satellites, as calculated from equation (1) with $q=1$, are shown in Fig. 2. It is immediately apparent from this figure that the distinctive pattern of the rings is reproduced well by the entire class of first-order resonances that fall in that interval and are associated with Ariel and Oberon and Ariel and Titania—the two pairs of satellites which, chiefly on the basis of the mass products shown in Table 1, we expect to have the greatest dynamical significance.

The systematic differences of several hundreds of kilometres between the two estimates of the ring radii are due to the fact that neither authors^{1,7} have yet made complete allowance for the motion of the Kuiper Airborne Observatory (KAO) and because the offset of the path of the occulting star from the centre of Uranus is imperfectly known. As the separation of the rings is small compared with their radii, however, the errors will be proportional to the radii, and we should expect a plot of one set of estimates against the other to be linear. By the same argument, a plot of each set of observations against the radii predicted by the resonances should also be linear, if indeed the proposed identifications of the resonances are correct. The observed linearity of these plots (see Fig. 3) therefore provides a strong argument in favour of the identifications.

The root mean square deviations from the least squares fits shown in Fig. 3 are 66 km in each case. As Marsden rounded off his estimates of the ring radii to the nearest hundred kilometres we can conclude that the fit of the points to a straight line is as close as could be expected, and thus different from our predictions only by a systematic offset. Elliot *et al.*¹ gave distances of the rings from the centre

Fig. 2 The two sets of preliminary estimates of the ring radii (labelled Elliot and Marsden) were calculated using the same set of occultation times. The systematic differences of several hundreds of kilometres are due to the fact that neither Elliot *et al.*¹ nor Marsden⁷ have yet made complete allowance for the motion of the Kuiper Airborne Observatory, and because the offset of the path of the occulting star from the centre of Uranus is imperfectly known. Resonant orbits for the dynamically more significant pairs of satellites are shown above the ring radii. The resonant orbits of Ariel and Oberon and of Ariel and Titania are shown on the same line for comparison of their distinctive pattern of three pairs with the observations; from left to right the first in each pair is the Ariel–Oberon and the second the Ariel–Titania resonance; the exact radii are listed in Table 2.

Fig. 3 Preliminary estimates of the radii of the observed rings, as calculated by Elliot *et al.*¹ and Marsden⁷, are plotted against the radii of the resonant orbits of Ariel and Oberon and Ariel and Titania. These radii, and the deviations from the above least squares straight line fits, are also listed in Table 2. A line of slope unity is shown for comparison. The quality of the straight line fit in each case indicates that a very consistent offset rather than a random relation exists between both sets of observational data and the radii predicted by the resonances.

of Uranus before immersion as well as after, and thus from their paper we can obtain two estimates of the ring separations which are independent of the assumed occultation midtime. These are listed in Table 3. The root mean square difference in the separations is 49 km. These differences would seem to be too large to be accounted for by any errors in the data reduction and would therefore indicate that the rings probably have eccentricities and inclinations of the order of 0.001 (these slight departures from exact circularity and coplanarity being generated by the resonant interactions between the ring particles and the perturbing satellites). But, again, we conclude that the straight line fit is as good as could be expected with the present level of observational uncertainty. We therefore conclude that the structure of the rings of Uranus has been determined by three-body resonances with the satellites Ariel, Titania and Oberon.

It seems not to have been noted before that these same three satellites are remarkably close to a first-order resonance condition themselves. In a frame rotating with Ariel, the innermost of the three, the ratio of the relative mean

Table 2 Radii of resonant orbits

Satellites	p	q	Radius* (km)	Deviations (km)	
				Elliot ¹	Marsden ⁷
Ariel, Titania	9	1	50,433	+78	+65
	10	1	47,451	–88	–119
	11	1	44,875	–58	–41
Ariel, Oberon	8	1	49,950	–48	–14
	9	1	46,651	+54	+44
	10	1	43,849	+60	+65

Table 3 Distances of rings from centre of Uranus*

Pre-immersion occultations	Ring separation, S	Post-emersion occultations	Ring separation, S'	S-S'
44,144		44,258		
	962		890	+72
45,106		45,148		
	1900		1939	-39
47,006		47,087		
	678		665	+13
47,684		47,752		

*The distances shown correspond with the values shown in Elliot, Dunham and Mink's Figure and were calculated from the times of the obscuring events quoted by Elliot *et al.*¹, assuming: a constant shadow velocity of 11.7 km s^{-1} ; a constant location on Earth; 25,900 km for the radius of Uranus; and an occultation midtime of 21 h 06 min UT.

motions of Titania and Oberon is 0.87414, differing from $7/8$ by one part in 10^3 . This close proximity to a similar resonance ($q = 1$, $p = 7$) as those of the rings suggests that Ariel may have formed from a similar ring, while the rings now remaining are inside or close to Roche's limit. Perhaps other satellites can be found in the locations given by other values of p in the same series.

Positional observations at the distance of Uranus performed with optical telescopes were previously limited to approximately 0.1 arc s, or 1,300 km. The cutting points of the rings and of the disk of Uranus in the occultation can, however, be determined to a much greater accuracy, possibly as good as 3 km (or 2.3×10^{-4} arc s). The identification of the resonances of the rings now allows their periods to be determined with the same precision as those of the satellites. Thus period and radius of orbiting objects will both be known to the new accuracy level, not limited as previously by the telescope resolution. Therefore it will be possible to improve the determination of the mass of Uranus by approximately two orders of magnitude. The knowledge of the planet's radius and its mean density would in any case have been greatly improved by the

occultation observation, but the knowledge of the resonance conditions will further improve these quantities and allow a better value to be obtained also for the dynamical oblateness, J_2 . With many more occultations that will now be useful, Uranus's system of satellites and rings may become the most accurately determined complex dynamical system.

The size distribution of the particles making up a ring of this type is determined by the magnitude of the drag forces and the strength of the resonance. If light-drag is responsible, then the strength of the resonance, which can be calculated by the methods of Greenberg³ and Sinclair⁴, will place a lower bound on the sizes of the trapped particles.

The fact that the Uranus system now provides at least six more examples of the type of three-body resonance described here, raises again the question of the importance that this orbital configuration may have had in the course of the evolution of the Solar System. Dermott (ref. 8 and in preparation) has shown that in the Solar System as a whole, that is, in the planetary system and in the satellite systems of Jupiter, Saturn and Uranus, there is a strong preference for pairs of mean motions, expressed in the rotating system of a third body, to be close to a first-order commensurability. We believe that we can account for the origin of the rings of Uranus by a mechanism of drag forces channelling material into the resonant orbits, as previously discussed by Gold². This suggests that this type of mechanism may have had an important role in the formation processes of the Solar System.

A consistent description of the nuclear α -decay process

Daphne F. Jackson & M. Rhoades-Brown

Department of Physics, University of Surrey, Guildford, UK

The essential features of a new theory of α decay and the need for such a theory are reviewed. An approximate relationship between half life and α -particle energy is deduced and checked for the decay of even polonium isotopes. Detailed calculations of one-body widths and spectroscopic factors for the polonium decays are presented and the implications of the results are discussed. It is also shown that the result for the α decay of ^{212}Po is consistent with the reverse α -transfer reaction.

THE process in which a nucleus in its ground or an excited state breaks up spontaneously into an α particle and a residual nucleus is the oldest observed reaction in nuclear physics. Gamow¹ gave a qualitative explanation of this process in terms of the quantum mechanical tunnelling of the α particle through the potential barrier formed by the sum of the real attractive

nuclear interaction between the α particle and the residual nucleus and the Coulomb repulsion between them. Combined with early studies of α -particle scattering from nuclei, this led to the first estimates of the size of the nucleus². Further development of these ideas based on the R-matrix theory of nuclear reactions have made possible satisfactory predictions of relative decay rates³. There has, however, been considerable difficulty and uncertainty in obtaining reliable predictions of absolute decay rates for heavy nuclei. The resolution of this problem has now become important because of the controversy over the possible existence of superheavy nuclei⁴ since the chance of observing these nuclei depends rather critically on their half life for α decay^{5,6}.

Predicting absolute decay rates

The difficulties associated with the prediction of absolute decay rates have two aspects. The nuclear structure part of the problem is concerned with the extent to which the α particle is

Fig. 1 The shape of the nuclear potential for the α particle in ^{212}Po .

performed in the nucleus; this is measured by the spectroscopic factor S_a which can be expressed as the ratio of the experimentally observed width Γ to the one-body width, that is

$$\Gamma = S_a \Gamma_{ob}, \quad \Gamma = \hbar/\tau \quad (1)$$

where τ is the observed mean lifetime. Within the framework of the shell model it is particularly difficult to show convincingly how the initial shell model state evolves into the final state consisting of the residual nucleus and a free α particle, and in almost all theoretical work using this model the initial and final states are not orthogonal. The nuclear reaction part of the problem is concerned with the emission of the α particle. This is frequently treated by means of the R-matrix theory in which the width Γ of a narrow resonance is proportional to the barrier penetrability P , which in turn depends on the channel radius R_c . The theory does not determine the value of this radius beyond the rather general requirement that it should be sufficiently large to exclude coupling between the various exit channels, and it is well known that a relatively small change in this radius can change the penetrability by an order of magnitude⁷. An approximate method of calculating the penetrability is given by the WKB approximation but this method underestimates the penetrability by at least a factor of five^{8,9}. A further substantial uncertainty in the calculation of the penetrability arises from ambiguities in the phenomenological optical potential which describes the interaction of a free α particle with the residual nucleus^{7,8}.

We have developed a theory of α decay which eliminates all arbitrary radii and ambiguous potentials and provides a consistent description of the initial and final states. It yields spectroscopic factors in agreement with other data but in marked disagreement with the predictions of the shell model. Other authors have attempted such an approach; in one case¹⁰ the arbitrary radius was eliminated but not the potential ambiguities which introduced variations as large as 10^3 in the calculated widths, while more recent work¹¹ removed much of the uncertainty in the potential barrier but retained an arbitrary radius and introduced new uncertainties arising from limited knowledge of the absorptive part of the potential.

The first step is to represent the initial state Ψ_i as an eigenstate of an unperturbed Hamiltonian K so that the difference between K and the exact Hamiltonian H is the perturbation which leads to α decay. An expression for the width Γ of the decaying state can then be obtained using time-dependent perturbation theory or using the unified reaction theory of Feshbach. Both methods yield, to first order⁹

$$\Gamma_{ob} = 2\pi \int dp(E_f) |\langle \Psi_f | H - K | \Psi_i \rangle|^2 \quad (2)$$

where Ψ_f represents the final state with energy E_f and $dp(E_f)$ is

the density of states per unit energy interval. The initial and final states are described by the cluster model, instead of the shell model. In the final state the free α particle interacts with the nucleus through an optical potential and this is calculated using forms for the basic α -nucleon interaction and the nuclear matter distribution of the residual nucleus which are in agreement with other experimental data. The height of the real potential barrier and the position r_b of the peak of the barrier are well determined from low energy α -particle scattering and consequently provided an important test of the calculated potential. For the initial system a bound state is artificially created by continuing the potential at a positive constant value beyond r_b , as shown in Fig. 1. The potentials for the initial and final states are identical for $R \leq r_b$ and the corresponding wave functions are orthogonal to a high degree of accuracy. The decay process arises through the perturbation which lowers the constant potential to its correct value, thus restoring the barrier and allowing the α particle to escape.

Polonium to lead decay

Calculations have been carried out for decays of even polonium isotopes to isotopes of lead, for which the lifetimes and α -particle kinetic energies are well known. For the $O^+ \rightarrow O^+$, $L = 0$, ground state to ground state transitions, equation (2) reduces to

$$\Gamma_{ob} = 2\pi \left| \int_{r_b}^{\infty} u_0(R) [U_{aA}(R) - U_{aA}(r_b)] \tilde{u}_0(R) dR \right|^2 \quad (3)$$

where $\tilde{u}_0$, u_0 are respectively the $L = 0$ bound and scattering wave functions of the α particle whose asymptotic forms are

$$\tilde{u}_0(R) \rightarrow e^{-\gamma R}, \quad \gamma^2 = \frac{2\mu}{\hbar^2} |E_{aA}| = \frac{2\mu}{\hbar^2} [U_{aA}(r_b) - T_a] \quad (4)$$

$$u_0(R) \rightarrow \sin(kR - n \log 2kR + \eta_0), \quad k^2 = \frac{2\mu}{\hbar^2} T_a \quad (5)$$

and U_{aA} is the sum of the nuclear and Coulomb interactions between the α particle and the residual nucleus A. Although there is some latitude in the description of the nuclear interaction because the basic α -nucleon interaction is not uniquely determined, this leads to a variation of only 20–40% in the spectroscopic factor, as indicated in Table 1. Thus the removal of the ambiguity in the potential and the arbitrary radius parameter R_c has eliminated most of the uncertainty in the calculation of α -decay rates, and more precise definition of the barrier height by other experiments would reduce this still further⁹.

Before examining the nuclear structure information represented by the spectroscopic factors we deduce the general relationship between lifetimes and α -particle energies predicted by this theory. In order to obtain such a relationship we neglect the nuclear potential beyond r_b so that

$$U_{aA}(R) - U_{aA}(r_b) = 2Ze^2 \left(\frac{1}{R} - \frac{1}{r_b} \right), \quad R \geq r_b \quad (6)$$

Table 1 Calculated values for decay widths and spectroscopic factors of $L = 0$ decays in polonium isotopes.

Isotope	T_a (MeV)	Potential*	Γ_{ob} (MeV)	$S_a = \Gamma_{exp}/\Gamma_{ob}$
^{210}Po	5.30	H	1.30×10^{-27}	0.029
		H'	1.64×10^{-27}	0.023
^{212}Po	8.80	H	1.02×10^{-14}	0.149
		H'	1.46×10^{-14}	0.104
^{214}Po	7.70	H	5.40×10^{-17}	0.053
		H'	6.80×10^{-17}	0.042

*The symbols H and H' represent different nuclear potentials.

The asymptotic form of $u(R)$ given by equation (5) is likely to be appropriate beyond the outer turning point r_t , which for $L = 0$ is given by $r_t = 2Ze^2/T_a$. Between r_b and r_t the WKB approximation can be used to give¹²

$$u^{(1)}(R) \sim A[K(R)]^{-1} \exp\left\{i \int^R K(r) dr\right\} \quad (7)$$

with $iK(r) = \beta(r)$, where

$$\beta^2(r) = \frac{2\mu}{\hbar^2} \left[U_{aA}(r) - T_a \right], \quad \beta^2(r_b) = \gamma^2, \quad \beta^2(r_t) = 0 \quad (8)$$

Since β^2 is slowly varying, we further approximate the scattering wave function to

$$u^{(2)}(R) \sim e^{i\beta(R)R} \quad (9)$$

so that expression (3) becomes

$$\Gamma \propto \left| \int_{r_b}^{r_t} e^{-\gamma R} \left(\frac{2Ze^2}{R} - \frac{2Ze^2}{r_b} \right) e^{i\beta R} dR + \int_{r_t}^{\infty} e^{-\gamma R} \left(\frac{2Ze^2}{R} - \frac{2Ze^2}{r_b} \right) \sin(kR - n \log 2kR + \eta_0) dR \right|^2 \quad (10)$$

Neglecting the second integral and retaining only the leading term of the first integral, we obtain the approximate expression for the half life T_1 ,

$$\log_e T_1 \propto \{A(T_a) + \log_e B(T_a)\} \quad (11)$$

where, with $x = 2Ze^2/r_b$

$$A(T_a) = 2\gamma r_t = \frac{2Ze^2}{T_a} \left(\frac{2\mu x}{\hbar^2} \right)^{1/2} \left(1 - \frac{T_a}{x} \right)^{1/2} \quad (12)$$

Fig. 2 Plot of $\log_{10} T_1$ for the experimental half lives of even polonium isotopes against $A(T_a)$ (dashed line) and against $A(T_a) + \log_e B(T_a)$ (full line). A value of $r_b = 10.8$ fm predicted by potential H has been used in the calculation.

Fig. 3 The angular distribution for the α -transfer reaction $^{208}\text{Pb}(^{16}\text{O}, ^{12}\text{C})^{212}\text{Po}$. The solid line, normalised to the data, represents the coherent sum of the normal DWBA contribution (the dotted line) and an additional contribution arising from our treatment of the α -decaying state (the other solid line).

$$B(T_a) = (\gamma r_b)^2 \left\{ 1 - \frac{r_b}{r_t} \right\}^{-2} = r_b^2 \left(\frac{2\mu x}{\hbar^2} \right) \left(1 - \frac{T_a}{x} \right)^{-1} \quad (13)$$

Although this dependence on T_a does not resemble any of the simple, empirical formulae previously given (see, for example, ref. 13), it can be seen from Fig. 2 that equation (11) does represent the behaviour of the observed half lives of the even isotopes of polonium which cover 14 orders of magnitude, despite the extreme approximations which have been made to derive it. We may reasonably expect that exact calculations using equation (2) should yield the correct lifetime-energy relationship in a wide range of circumstances.

For the particular case of the α decay of the ground state of ^{212}Po to the ground state of ^{208}Pb , which has been widely studied, we obtain spectroscopic factors S_a in the range 0.10–0.15. These values are in excess of the predictions of the shell model (A. Arima and I. Tonozuka, personal communication) by at least two orders of magnitude. It therefore seems that the shell model is inadequate for this nucleus. The most extreme cluster model in which the cluster expansion is reduced to a single term would yield a spectroscopic factor of unity. The small value of S_a obtained for ^{210}Po reflects the need to break the neutron closed shell to remove an α particle, and here the shell model concept is important.

Checking the results

In order to test our results against different data, we have just completed¹⁴ a study of the reaction $^{208}\text{Pb} + ^{16}\text{O} \rightarrow ^{12}\text{C} + ^{212}\text{Po}$ (gs). In this process an α particle is transferred into ^{208}Pb and it is therefore the inverse of the α -decay process. The initial and final states of the heavy nuclei were described in exactly the same way as in the α -decay calculation. The ^{16}O projectile was

described by the model of Kurath¹⁵ which yields a spectroscopic factor of 0.23 for $^{16}\text{O} \rightarrow ^{12}\text{C} + \alpha$. The spectroscopic factor for $^{212}\text{Po} \rightarrow ^{208}\text{Pb} + \alpha$ was then found by making a distorted wave fit to the angular distribution¹⁶ for the transfer reaction. As can be seen from Fig. 3, the fit to the data is good; it yields a spectroscopic factor of 0.14–0.21 which is in good agreement with the value obtained from α decay.

An alternative means of checking the predicted spectroscopic factors is to calculate them directly using the same nuclear model. We have done this for the 18^+ isomeric state in ^{212}Po which decays to the 0^+ (gs), 3^- and 5^- states in ^{208}Pb . Proceeding as before we find that the spectroscopic factor for the decay to the ground state is 0.13 while a simple perturbation calculation gives the parentage of this stage in the cluster model expansion as 0.25. This is satisfactory agreement given the simplicity of the cluster calculation. The ratio of our calculated one-body widths for the decay of ^{212m}Po and ^{212}Po to the ground state of ^{208}Pb is in very close agreement with experiment where, in contrast, shell model calculations using R-matrix theory¹⁷ are greater than experiment by up to a factor of 45, depending on the channel radius. For the transitions to the lowest 3^- and 5^- states we included in our expansion of the initial state only the 0^+ , 3^- and 5^- states of the residual nucleus. The excitation potentials were parametrised directly in terms of the derivatives of the optical potential with the appropriate transition strength taken directly from inelastic α -particle scattering¹⁸. The encouraging results for this calculation, in contrast to the shell model calculations with varying degrees of configuration mixing¹⁷, suggest that what is important in the decay of the isomeric state is not the collective excitation of the residual

nucleus but rather the cluster structure of the decaying state ^{212m}Po .

All the calculations reported here have been restricted to the expected dominant terms in the cluster model expansion but the formalism will allow the study of many additional effects. Our results also suggest that the very complicated many-body structure of the initial state and the formation of the α -particle are more accurately represented by a cluster model expansion. So far, familiar decay processes have been chosen for study in order to eliminate arbitrary parameters, but there is sufficient information on α -particle decay energies and potential energy surfaces available for superheavy nuclei to make possible a much more realistic estimate of α -decay lifetimes in superheavy nuclei.

letters to nature

Two new D2 QSOs

MOST extragalactic radio sources fall into one of two categories. In one the emission is extended, with two main peaks tens or hundreds of kiloparsecs apart straddling the associated optical object, while in the other the source is compact (typically less than a kiloparsec in size), with optical and radio positions that coincide to within the errors of measurement. More rarely, double sources may belong to a third category, which was classified by Miley¹ as D2, and of which the type example is 3C273. Sources of this class consist of a small variable nuclear component coincident with the optical object, and a second, larger component with a much steeper spectrum. We report here high resolution observations made with radio-link interferometers based on Jodrell Bank which show that the QSOs 3C345 and 3C454.3 have extended radio structure similar to that of 3C273. Hence these sources, previously believed to be compact, should also be classified as D2. Details of the observations are given in Table 1.

Observations at high frequencies^{2,3} with a resolution of a few arc s detect only compact nuclear components in 3C345 and 3C454.3. Our observations show that the nuclear component of 3C345 is unresolved, with an angular size $\theta < 0.1$ arc s, but suggest that the nuclear component of 3C454.3 is extended, with $\theta \sim 0.5$ arc s in position angle $130 \pm 5^\circ$. High resolution VLBI observations⁴ detect fine structure on a scale of about 10^{-3} arc s in both nuclei. The positions of the nuclear components from our observations⁵ agree well with the radio positions by Elsmore and Ryle³,

and by Rogers *et al.*⁶, and with the optical positions of the QSOs⁷.

In addition to the nuclear components, our observations reveal extended emission from a steep-spectrum companion component in each source. The variations with hour angle of the interferometer fringe amplitude for each baseline listed in Table 1 have been fitted by models which assume components with elliptical Gaussian profiles. The component separations are well determined and do not vary with frequency. The sizes of the individual components themselves, however, are less certain. The best fitting model for the structure of each source is shown schematically in Fig. 1, with details given in the legend. The angular separation of the components corresponds to a projected separation at the source of 14 kpc for 3C345, and 39 kpc for 3C454.3, assuming a Friedmann cosmology with $q_0 = +1$ and $H = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$. The corresponding value for 3C273 is 70 kpc.

Table 1 Observations

Frequency (MHz)	Interfero- meter baseline (km)	Minimum lobe size (arc s)	Epoch of observations	
			3C345	3C454.3
408	24	6.3	1969.9 (ref. 16), 1971.7, 1972.7 1971.7	
408	127	1.2	1970.9 (ref. 17)	1974.7, 1975.9
962	24	2.7	1973.9	1973.9
1,666	24	1.6	1973.3	1973.3
1,666	127	0.3	1974.8 (ref. 18)	

Fig. 1 The radio structures of 3C345 and 3C454.3. North is to the top, increasing Right Ascension to the left. In each source the nuclear component is distinguished by a cross. The components of 3C345 have a separation of 2.1 ± 0.1 arc s in p.a. $149 \pm 6^\circ$. The nuclear component is smaller than 0.1 arc s in all directions; the companion component has a size of $\sim 2.5 \times 0.5$ arc s and is elongated in p.a. $142 \pm 6^\circ$. The components of 3C454.3 have a separation of 5.4 ± 0.1 arc s in p.a. $131 \pm 1^\circ$. The nuclear component has a size of $\sim 0.5 \times < 0.3$ arc s and is elongated in p.a. $130 \pm 5^\circ$; the companion component has a size of $0.7 \times < 0.3$ arc s and is elongated in p.a. $165 \pm 10^\circ$.

Marked variations have been reported in the flux density of 3C454.3 at frequencies below 1 GHz (refs 8, 9). The 408-MHz flux density was 14.0 ± 0.7 Jy at epochs 1971.7 and 1972.7, but had risen to 15.9 ± 0.7 Jy in 1974.7, and was 14.8 ± 0.7 Jy in 1975.9 (flux densities on the KPW scale¹⁰). The fringe amplitude data indicate that it is the nuclear component alone which is responsible for these variations. Our measurements of 3C345 are less extensive but suggest that neither component of this source varied by more than 10% in the 2-yr period of our observations at 408 MHz.

The flux densities of the components of 3C345 and 3C454.3 are shown in Fig. 2 together with the integrated spectrum^{11,12} of each source. Both nuclear components have slightly inverted spectra in the range 408–1,666 MHz, whereas the companion components have steep spectra, with spectral indices -1.4 ± 0.2 and -1.0 ± 0.1 respectively. It is clear from Fig. 2 that the rise in flux density at the low-frequency end of the integrated spectrum may be attributed to the companion component in each case. It may well be that other QSOs with D2 structure could be recognised from the shape of their integrated spectra.

Fig. 2 The radio spectra of 3C345 and 3C454.3. The continuous curves are the integrated spectra from refs 11 and 12. The spectra of the nuclear and companion components are labelled *a* and *b* respectively. The points at 2,695 MHz have been obtained by re-interpreting the visibility data of Bash² in terms of our model structures.

It is interesting to note that 3C273, 345 and 454.3 are all optically violently variable¹³. In the case of 3C273 the companion radio component is associated with a faint optical jet^{14,15}. By analogy, it may be worthwhile to search for optical counterparts to the companion radio components of 3C345 and 3C454.3. There are however considerable practical difficulties in detecting faint optical jets only a few arc s away from ~ 16 mag QSO nuclei.

Nova shells: matter-bound or radiation-bound?

THE ionisation structure of nova shells is quite uncertain. Many recent papers^{1,2,11} have assumed that the shell is fully ionised during the decline, and that the rate of decline is a sensor of the matter density in the expanding shell. In this letter we propose that the shell of V1500 Cyg is not fully ionised, but rather forms a Strömgren shell. In this case the optical light curve is determined by the decline of the energy production rate of the central object.

The spectrum of a typical fast nova (V1500 Cyg, CP Pup, CP Lac) during outburst is first characterised by a moderately hot ($\sim A$ type) optically thick photosphere. The expanding material becomes optically thin after maximum^{1,11} and after a certain time, which varies from nova to nova, the spectrum changes to that of an H II region or planetary nebula.

Recent papers have assumed that the expanding shell is completely ionised during this nebular phase. In this case the size of the emitting region is determined only by the spatial extent of the shell: the emitting region is said to be matter-bound. The hydrogen emission from a matter-bound envelope is given by

$$E \propto \int N_e N_p a_{ff}(T) dV + \int N_e N_p a_{fb}(T) dV \quad (1)$$

where the electron and proton densities are particles cm^{-3} and the temperature sensitive free-free and free-bound cross sections have the usual definition. We have neglected the effects of line optical depth.

If the shell is homogeneous and hydrogen is the dominant electron donor then equation (1) simplifies to

$$E \propto N_e^2 V \quad (2)$$

For a completely ionised nebula the electron density is directly proportional to the local matter density so we can write

$$E \propto \rho^2 V \propto V^{-2} V \propto V^{-1} \propto t^{-\beta}$$

where t is time. The expansion law is determined by β ; $\beta = 2$ for a thin shell expansion (linear thickness of the shell is independent of time), and $\beta = 3$ for a Hubble law expansion ($\delta r/r = \text{constant}$). The latter may be more appropriate for an explosion. We see that the emission from a matter-bound shell is determined mainly by the matter density. Actually there is also a temperature dependence because of the temperature-sensitive cross sections.

The time of onset of the expansion of a matter-bound shell may be determined from the light curve². The times of onset derived with this technique are typically about one month before optical maximum.

The size of the photosphere at maximum is a simple test of the plausibility of this model. Using V1500 Cyg as an example and assuming that the main shell was ejected 35 days before maximum² at a velocity of 1,500 km s⁻¹ (ref. 3) we find that the optically thick photosphere would have a radius of over 30 AU at maximum, about ten times larger than observed¹. This hypothesis is also in substantial disagreement with the observed blackbody expansion curves^{1,4}.

In this letter we question the basic assumption that the shell is matter-bound. Following the work of Pottasch⁵ we propose that the shell is radiation-bound, that is, that the volume of the emitting region is determined by the balance between photoionisation and recombinations. The most direct evidence that the V1500 Cyg shell was not fully ionised is the observation³ of neutral oxygen emission long after maximum. This was observed both as [O I] 6300, 6363 (ref. 6) and O I 8446, 7774 (ref. 9).

We shall consider the ratio of flux in H β to that in [O I] 6300. This ratio was ≈ 10 for much of the decline⁶. We shall predict this ratio for a fully ionised shell in the following manner. The H β emission from an optically thin unit volume is

$$E(\text{H}\beta) = h\nu_{\beta} N_e^2 \alpha_{\text{H}\beta}^{\text{eff}} = h\nu_{\beta} N_e^2 3.1 \times 10^{-14} \text{ cm}^3 \text{ s}^{-1} \quad (3)$$

where we have assumed a temperature of 10⁴ K and an effective case B recombination coefficient⁷. An upper limit to the energy in λ 6300 may be estimated by assuming that the ¹D₂ level is populated as in LTE at 10⁴ K. The emission from the thermalised ¹D₂ level will be

$$\begin{aligned} E(6300) &= h\nu_{6300} N(\text{O I}) g/U(\text{O I}) e^{-h\nu/kT} A(6300) \\ &= h\nu_{6300} N(\text{O I}) 3 \times 10^{-4} \end{aligned} \quad (4)$$

where we have again assumed a temperature of 10⁴ K. The intensity ratio will be

$$\frac{E(\text{H}\beta)}{E(6300)} = \frac{6300}{4861} N_e^2 N(\text{O I})^{-1} 1 \times 10^{-10} \quad (5)$$

We can predict the fractional abundance of O I by assuming that it is coupled to the fractional abundance of H I by charge exchange

$$\frac{N(\text{O I})}{N(\text{O II})} \approx \frac{9}{8} \frac{N(\text{H I})}{N(\text{H II})} = \frac{9}{8} \frac{\xi}{(1-\xi)} \approx \frac{9}{8} \xi \quad (6)$$

where ξ is the fraction of neutral hydrogen and we anticipate our result that hydrogen is highly ionised. An upper limit to

the oxygen emission can be obtained by assuming that all oxygen is in one of these two species.

We can estimate ξ by equating photoionisation with recombinations and assuming steady state. The balance equation at a typical point in the shell is

$$N(\text{H I}) \sigma \frac{Q(\text{H}) e^{-\tau}}{4\pi r^2} = N_e^2 \alpha_{\text{B}}(I) \quad (7)$$

where σ is the target area for photoionisation ($\approx 6 \times 10^{-18} \text{ cm}^2$), $Q(\text{H})$ is the number of ionising photons emitted by the central object, τ is the optical depth to ionising photons (for a matter-bound shell τ is small so we shall take $e^{-\tau} \approx 1$), and r is the radius of the shell. We will evaluate the parameters at a time 30 d after the outburst. Assuming an expansion velocity of 1,500 km s⁻¹ we obtain a radius of $4 \times 10^{14} \text{ cm}$. Unpublished McDonald scans show that H β had a strength of $5 \times 10^{-17} \text{ J s}^{-1} \text{ cm}^{-2}$ which corresponds to $2.6 \times 10^{17} \text{ photon s}^{-1}$ if we assume¹⁰ a colour excess of $E(B-V) = 0 \text{ mag. 50}$ and a distance of 1,800 pc. The assumption that the shell is matter-bound requires that $Q(\text{H})$ be much larger than the photoionisation rate of $2.6 \times 10^{17} \alpha_{\text{B}}/\alpha_{\text{H}\beta}^{\text{eff}} \approx 2.4 \times 10^{18} \text{ s}^{-1}$. Using these parameters we obtain

$$\frac{N(\text{H I})}{N_e^2} = \frac{\alpha_{\text{B}}(T) 4\pi r^2}{\sigma Q(\text{H})} = 6 \times 10^{-14} \text{ cm}^3$$

or

$$\xi = N_e 6 \times 10^{-14} \approx 10^{-5}$$

where we have assumed an electron density of 10⁸ cm⁻³. The ratio of line strengths will be

$$\frac{E(\text{H}\beta)}{E(6300)} = \frac{N(\text{H})}{N(\text{O})} 7.3 \times 10^{-5} N_e \approx 0.02 N_e \approx 10^6$$

where we have included solar abundances⁸. We see that the observed strength of [O I] 6300 is five orders of magnitude stronger than the predicted value for a fully ionised shell. Enhanced oxygen abundances cannot resolve this discrepancy.

The observed strength of O I is easily understood if the shell is radiation-bound. The O I emission originates at the edge of the hydrogen Strömgren sphere where both free electrons and neutral oxygen are abundant.

The presence of an H Strömgren sphere has important consequences. The optical emission from the envelope will be a sensitive indicator of the emission of the central object at frequencies below the H ionisation threshold since the radius of the Strömgren sphere adjusts itself so that the number of photoionisations equals the number of recombinations. Thus we see that published light curves² of nova shells which are optically thin in visible radiation but which are optically thick to ionising photons are valuable indicators of the decay of energy generation of the central object. The cool outer neutral zone may also provide an auspicious site for the dust formation which seems to be a common feature of the nova outburst¹¹.

I thank Drs J. Tomkin, D. L. Lambert, G. Shields, and H. A. Wooten for discussions.

Effect of electrojet on the total electron content of the ionosphere over the Indian subcontinent

THE radio beacon method of measuring TEC along a chain of optimally spaced stations near the equatorial anomaly has been used to monitor continuously the latitudinal extent of the anomaly. Comparisons with the magnitude of the electrojet show a clear dependence of anomaly strength upon the electrojet intensity with an approximate two-hour time delay.

Anomalous latitudinal distribution of electron density in the F2 region, often referred to as the equatorial anomaly, was found by Appleton¹. The diurnal development of the equatorial anomaly has been studied by Rastogi². Dunford³ showed that the equatorial anomaly in the topside ionosphere is correlated with the E region current system near the magnetic equator. With the development of the satellite radio beacon technique numerous workers⁴⁻⁹ studied the Appleton anomaly in total electron content (TEC) of the ionosphere with greater spatial resolution, but with poor temporal resolution, as only a few passes per day of the low orbit satellite could be received. Iyer *et al.*¹⁰ showed that the equatorial anomaly in TEC over India is positively correlated with the electrojet strength. The diurnal development of the equatorial anomaly in TEC is presented here for the first time; and, along with magnetometer records which indicate the strength of the equatorial electrojet, the TEC anomaly is shown for three days in May 1976. The equatorial anomaly in TEC was continuously monitored over the Indian subcontinent using radio beacon signals from the geostationary satellite ATS-6, received at many locations in India, namely: Bombay (19.8°N, 69.8°E), Rajkot (20.8°N, 67.7°E), Ahmedabad (21.5°N, 69.4°E), Udaipur (22.9°N, 70.2°E), Jaipur (25.1°N, 71.9°E), and Patiala (28.2°N, 72.1°E). Coordinates given are 350-km intersections along the ray path to the ATS-6 satellite. Details of the stations in the Indian subcontinent measuring TEC using ATS-6 beacon transmissions have been given by Iyer *et al.*¹¹.

The diurnal development of the equatorial anomaly in TEC and its association with electrojet strength are clearly shown in Fig. 1. Three typical cases are chosen: (1) a normal electrojet day, 18 May 1976, $A_p=3$; (2) a counter electrojet day, where the counter electrojet occurred in early afternoon, 12 May 1976, $A_p=7$, and (3) a geomagnetically disturbed day, 3 May 1976, $A_p=94$. For all three days the horizontal component of the magnetic field (H) for an equatorial station, Kodaikanal, dip 3.4°N, are also shown. The magnetic field during daytime is a representative indication of the electrojet strength. In addition TEC plots against latitude are shown for different local times of the day. On a normal electrojet day the magnetic field shows a flat minimum night value (Fig. 1a). After sunrise the electron density in the E region increases and the H field shows a steady increase until around 1100 h, after which it starts decreasing. Such behaviour of the magnetic field is due to the eastward electric field (E) during daytime. Owing to this electric field and the north-south magnetic field at the equator $E \times B$ drifts are produced and the electrons are lifted to higher altitudes. The lifting of electrons takes place up to a few scale heights above the F2 region peak, beyond which they diffuse along the lines of force and are deposited in the latitude regions of about 15° to 20° dip latitude. This process takes approximately

Fig. 1 Diurnal development of equatorial anomaly and strength of electrojet. a, Normal electrojet day. Note that the anomaly is fully developed during afternoon hours. b, Counter-electrojet day, where anomaly is reduced during afternoon hours. c, Disturbed day, where anomaly is not at all developed.

2 h (ref. 10) and any effects in electric fields at E region heights at the equator are seen at latitudes of 15° to 20° after an approximate two-hour delay. At 1000 h, the latitudinal profile of TEC is showing a normal behaviour with high equatorial values (Fig. 1a). As time progresses, at 1200 h, a weak anomaly develops with maximum TEC at Udaipur. By 1400 h more electrons have flowed along field lines to Udaipur and the anomaly is well developed. The process continues until evening and a clear maximum is still seen at 1730 h at Udaipur on this normal electrojet day.

The H component of the equatorial magnetic field shows the start of a normal electrojet in the forenoon hours (Fig. 1b). However, at approximately 1340 h the direction of the H component reverses and a counter electrojet has begun. The latitudinal profiles of TEC for several times on 12 May show a small latitudinal anomaly at 1200 h, reaching a maximum at 1400 h, at the Rajkot ionospheric intersection point (Fig. 1b). But, by 1600 h, and later at 1730 h, there is little, if any, trace of the anomalous latitudinal behaviour in TEC, due to the counter electrojet which developed in early afternoon. The reversal of the

electric field causes downward drift motion at the equator and the movement of ionisation to the latitude range of 15–20° becomes ineffective. The approximate two-hour delay between the start of the counter electrojet and the near-end of the latitudinal TEC anomaly is clearly seen in Fig. 1b.

Data for a highly geomagnetically disturbed day, 3 May 1976, are also shown (Fig. 1c). On this day the electrojet does not occur and the transfer of ionisation from the equator to higher latitudes does not take place to any noticeable extent.

Hydrothermal plumes in the Galapagos Rift

ALTHOUGH there is indirect evidence that a major fraction of the heat loss from newly-created lithosphere occurs by convection of seawater through the porous crust^{1–3}, it has proved difficult to locate vents of deep-sea hydrothermal systems by direct measurement of the discharge fluid. Local increases in bottom water temperature up to 0.1 °C have been measured by towing arrays of thermistors a few metres above the axes of active oceanic spreading centres^{4,5}, but these data are ambiguous because small temperature anomalies may have a hydrographic explanation. We report here the first conclusive measurements of modified seawater discharging as buoyant hydrothermal plumes from fissures in young oceanic crust. We obtained samples of hydrothermal plumes in the Galapagos Rift⁶, albeit after considerable dilution with surrounding bottom-water, and report the first results of the collection and analysis of these samples.

Our initial estimates of properties useful for detecting deep-ocean hydrothermal fluids were based on the geochemistry of the Red Sea brines^{6,7}, the only oceanic geothermal system previously sampled. In this system the basalt-interaction imprint is unfortunately superimposed on a saturated brine because the seawater flows through evaporite deposits before entering the basalts⁸. Predicted concentrations for constituents masked by the evaporite contribution must therefore be based on laboratory measurements⁹. Our estimates showed that helium isotopes were by far the most sensitive geochemical tracers: a mixture of one part of hydrothermal fluid in ~10⁵ parts of seawater should be detectable in the ³He/⁴He isotope ratio, while a dilution of ~2×10⁴ should be detectable with total helium concentration. The latter figure is comparable with the detection limit for temperature differences, assuming a 50 °C fluid temperature. Transition metals such as Mn and Fe are also highly enriched in the Red Sea brines but the observed enrichments are consistent with an origin from evaporites⁹ and ³He is the only tracer which cannot be derived from such a source⁷.

During the May 1976 Pleiades Expedition of the Scripps Institution, near-bottom hydrographic and geochemical surveys of sites on the East Pacific Rise (4°S, 102°W) and in the Galapagos Rift (1°N, 86°W) were made with a remote sensing and sampling system attached to the deep tow geophysical vehicle of the Scripps Marine Physical Laboratory⁹. The geochemical system included a high-precision CTD instrument to measure conductivity, temperature, and pressure, a light transmissometer, and an array of 8 remotely-triggered 9-litre sampling bottles designed for rapid flushing. The data were telemetered to a shipboard computer which continuously monitored depth, potential temperature (θ), salinity (S), potential density at 4,000 decibars (σ_t), and light transmission in real time. Measurement precision was ± 1 m in depth, ± 0.0015 °C in θ , and ± 0.002 ‰ in S . At each site the instrument package was towed ~8–100 m above bottom at speeds of ~1–2 knots (30–60 m min⁻¹) for about four days, using acoustic transponders for navigation and sonars and cameras for mapping bottom topography.

Near-bottom potential temperature excursions or 'spikes' were encountered in both survey areas; two examples are shown in Fig. 1 (upper traces). Hydrographic or mixing spikes ('false plumes') were characterised as such in the following way. The temperature-salinity (θ - S) relationship for the local water mass was first established by continuous soundings with the vehicle. The observed θ - S relationship (linear at the spreading axis depth) was then programmed into the computer and the appropriate function of θ , S which is invariant to mixing was monitored continuously. Deviations from this relationship were assumed to represent possible hydrothermal plumes and sampling was triggered manually when such deviations were observed.

Fig. 2 shows θ - S data points collected over several hours of towing during the East Pacific Rise survey. Bottom water temperatures west of the rise in this area are ~0.1 °C lower than at comparable depths east of the rise, while at the crest itself there is a transition region which is actually a sharp benthic thermocline (Fig. 2a). Fig. 2b, which contains all the rise-crest data from Fig. 2a, shows that only a single water mass, characterised by a linear θ - S relationship, is present over the entire region. The transition region at the rise crest thus simply reflects linear mixing between the water types on either side of the crest; as the deep tow vehicle navigates through the rough topography the θ record exhibits spikes caused by vertical excursions of the sensor and by encounters with various members of the continuous array of water types available in eddies and streams on the crest. Heated bottom water, however, will deviate from the ambient

Fig. 1 Temperature records from an arbitrary time zero as the deep tow vehicle is towed ~ 10 m above bottom. Upper traces: potential temperature (θ) plotted at 10 points s^{-1} , corrected for a 200-ms time constant and smoothed by 10-point running average. Lower traces: the θ -salinity function ($\theta + XS$), which is invariant to mixing, with similar correction and smoothing. *a*. A record taken 1.9 km west of the East Pacific Rise axis, shows a 'false plume' in which the temperature spike is not seen in the θ - S function and is thus due to mixing. Tow speed was 50 $m\ min^{-1}$. *b*. The Galapagos Rift site data show a true hydrothermal spike which is reflected in both the temperature and $\theta + XS$ records. Tow speed was 43 $m\ min^{-1}$ and sample 7-0 was collected during the interval shown beneath the θ record.

θ - S relationship characterised by $\theta + XS = \text{constant}$, where X is the negative slope on the θ - S plot (Fig. 2b). Because of the possibility of conductive heating, the detection of such a ' θ - S spike' is a necessary, but not sufficient, con-

dition for the existence of an actual hydrothermal plume.

The lower trace in Fig. 1a is the real time record of the θ - S function measured concurrently with the East Pacific Rise θ record shown above, and plotted to the same

Fig. 2 Near-bottom (10-100 m) potential temperature data points measured over several hours of towing at the East Pacific Rise survey site, plotted against depth (Fig. 2a) and salinity (Fig. 2b). The θ - S diagram (2b) shows that the entire array of water types represents a single water mass; the θ - S slope here ($= -X$) is -22 .

Fig. 3 Locations of hydrothermal plumes observed in the Galapagos Rift, with topography summarised from a deep tow structural map¹⁴. Numbers refer to plumes actually sampled. In addition to the axial fissures shown there are many fissures and minor faults along the minor rift margins; no plumes were detected in these marginal areas.

vertical scale. This spike is clearly due to mixing and is labelled a 'false plume'. It is apparent that a ' θ -S spike' requires an amplitude of $>0.02^\circ$ for detection due to the scatter introduced by the conductivity measurement. Within this limitation, no hydrothermal spikes were observed during the East Pacific Rise survey.

Fig. 1b shows a potential temperature spike measured on the Galapagos Rift which shows a corresponding excursion in the θ -S function. In this area the near-bottom temperature structure reflects mixing between bottom water entering the Panama Basin through the Ecuador Trench¹⁰ and warmer overlying water which spills across the Carnegie Ridge¹¹. The θ -S excursion shows clearly that in this case the θ anomaly is not caused by mixing. Sample 7-0, collected somewhere in the indicated time interval, had a $^3\text{He}/^4\text{He}$ ratio equal to twice the atmospheric ratio, a spectacular anomaly relative to 'background' water which has a ratio only 30% greater than atmospheric¹². This is by far the largest $^3\text{He}/^4\text{He}$ ratio yet observed in deep ocean water and there is thus no

doubt that an actual hydrothermal plume was sampled.

Fig. 3 shows the bathymetry of the Galapagos Rift area as surveyed during the present study. The lava flows in the inner rift valley are fractured by many small faults and fissures along the rift margins, but near the central axis fracturing is confined to a few fissures about two or three metres wide extending along the central high^{13,14}. Ten temperature spikes with corresponding ' θ -S spikes' were observed in this region during the shipboard survey; the locations of these ten spikes are plotted in Fig. 3 which shows that all ten lie on the axial fissure in the centre of the inner rift. Three of these spikes, 7-0 (the largest of the ten spikes) 8-3, and 8-6, were sampled and analysed; all three showed $^3\text{He}/^4\text{He}$ and radon anomalies relative to background water, verifying that the θ -S excursions in these ten locations represent true hydrothermal plumes.

A preliminary analysis of the remaining tow data has shown no evidence of hydrothermal activity off the central axis of the Galapagos Rift. One area of special interest

in our survey was a region of 5–20 m high sediment mounds ~30 km south of the central axis which have been described as possible hydrothermal vents¹². In this area the water structure is so uniform that hydrothermal spikes of ~0.002 °C should be observable, yet even with this sensitivity there was no evidence of hydrothermal plumes associated with the mounds.

Several of the hydrothermal plumes showed a small decrease (~0.1%) in light transmission; filtrates from the three sampled plumes and water have been distributed for a number of geochemical measurements. The helium and radon measurements are described in an accompanying paper¹². Our results show that there is a one-to-one correspondence between the hydrographic identification of samples as heated water and the presence of excess quantities of ³He/⁴He and Rn in these samples. Together, these results constitute the first conclusive identification and sampling of hydrothermally circulating seawater in a deep-ocean spreading centre. Based on these findings, a detailed study of the Galapagos Rift hydrothermal vents using a manned submersible is now in progress.

We thank F. N. Spiess, J. Spiegelberg, J. Jain, and the entire Deep Tow technical group for their support, interest and assistance. Financial support for this research was provided by the US NSF.

Mantle helium in hydrothermal plumes in the Galapagos Rift

THE ³He/⁴He ratio in deep Pacific water is 20–30% higher than in atmospheric helium because of injection of primordial helium from the mantle^{1,2}. The largest ³He enrichments in the Pacific have been found in water on the crest of the East Pacific Rise where the isotopic ratios indicate² that the excess helium component has a ³He/⁴He ratio about ten times the atmospheric ratio, in agreement with the ratios measured in trapped helium in the glassy rims of oceanic tholeiites^{3,4}. Recent measurements in this laboratory⁵ have shown that the hot brines in the axial rift of the Red Sea are very highly enriched in mantle helium. ³He and ⁴He are respectively 3300 and 380 times supersaturated relative to atmospheric solubility equilibrium in seawater, with a ³He/⁴He ratio of 1.2 × 10⁻⁵, or 8.6 times the ratio in atmospheric helium. Comparison of the enrichments of various elements in the Red Sea brines and

in brines associated with salt domes⁶ shows that helium is the only component in the Red Sea brines which unequivocally requires derivation from hydrothermal circulation of seawater in basalts. The helium isotopes are thus an extremely powerful and sensitive tracer for the detection and mapping of hydrothermal systems in oceanic spreading centres.

The Red Sea brines represent an extreme example of the most probable mechanism for the actual injection of mantle helium into the deep sea, namely the penetration and hydrothermal circulation of seawater in basalts on the crests of mid-ocean rises. In the Red Sea the circulating fluid is a brine because the downward penetrating seawater encounters evaporites before reaching the basalt⁶, and thus the upward convecting fluid is stabilised in brine pools in depressions on the sea floor. In normal oceanic spreading centres, however, where evaporites are absent, the heated seawater should emerge as hydrothermal plumes which should be detectable by the association of temperature anomalies with the mantle helium signature. In this letter we report the first ³He measurements on such plume samples, showing that hydrothermal circulation of seawater in basalts is an active process at spreading centres which transfers mantle helium to deep ocean water.
